SUPPLEMENT 270

Frontal Sinus Surgery

BY

ROGER HAYS LEHMAN

Presented as Candidate's thesis to the American Laryngological,
Rhinological and Otological Society October 1969

Veterans Administration Center and Marquette University School of Medicine,
Milwaukee, Wisconsin, USA

I Introduction

Frontal sinus surgery comprises only a small part of the current otolaryngologic practice. The classical clinical pictures of acute and chronic suppuration have been modified by the antibiotic and chemotherapeutic agents. Lack of symptoms and absence of signs have made specific diagnoses more difficult. Latent infections do exist, and the probability of intracranial complications arising from them is still very real.

Early surgical procedures were radical and designed to prevent intracranial complications. The functional and cosmetic results left much to be desired. An era of conservatism in surgery

followed the advent of the antibacterial drugs. Upon recognition of increasing numbers of patients with residual disease and complications, reports of more extensive surgery began to appear. There has been a recent revival and modification of older techniques with improved results.

A current review of frontal sinus surgery performed over a period of two decades seems appropriate at this time. Consideration will be given to the historical background, surgical anatomy, physiologic principles, and operative procedures.

II History

In 1870 Wells (1) reported a patient with a pyocoe involving the fronto-ethmoid cell complex who was cured by an external and internal nasal drainage procedure.

Opston (2) in 1884 advocated trephining of the frontal sinuses for catarrhal diseases unresponsive to medical therapy. He used a midline vertical incision, elevated the periosteum, entered the sinus with a sixpenny size trephine craniotome, and enlarged the opening with a hand. Diseased mucous membrane was removed, and a drainage tube was placed into the nose. Three patients described were asymptomatic for a considerable period of time.

Obliteration of the frontal sinus performed by Kuhn (3) in 1895 included removal of the anterior wall, paring 0.5 cm above the orbital margin. He cited Runge as performing a similar operation 150 years earlier and quoted techniques of his contemporaries, Hebling & Jan-

sen, who recommended intranasal drainage. Kuhn, however, favored external drainage above and daily postoperative irrigations of the cavity with sublimate.

Röpke (4) in 1898 modified the procedure by removing the anterior, inferior and medial walls of the frontal sinus to expose adequately involved ethmoid cells. Riedel (5) stressed the importance of taking the inferior sinus wall.

The osteoplastic anterior wall approach to the frontal sinus was described by Schönborn (6) in 1894. Brieger (7), in 1895, reported upon the use of a skin-periosteum-bone flap which was successfully removed and reimplanted. In 1904 Winckler (8) suggested an osteoplastic procedure with the flap hinged above the orbital margin. He used this approach only when no bone or soft tissue was involved by disease and when no intracranial complications were suspected. Beck (9) and

I Introduction

Frontal sinus surgery comprises only a small part of the current otolaryngologic practice. The classical clinical pictures of acute and chronic suppuration have been modified by the antibiotic and chemotherapeutic agents. Lack of symptoms and absence of signs have made specific diagnoses more difficult. Latent infections do exist, and the probability of intracranial complications arising from them is still very real.

Early surgical procedures were radical and designed to prevent intracranial complications. The functional and cosmetic results left much to be desired. An era of conservatism in surgery

followed the advent of the antibacterial drugs. Upon recognition of increasing numbers of patients with residual disease and complications reports of more extensive surgery began to appear. There has been a recent revival and modification of older techniques with improved results.

A current review of frontal sinus surgery performed over a period of two decades seems appropriate at this time. Consideration will be given to the historical background, surgical anatomy, physiologic principles, and operative procedures.

II History

In 1870 Well (1) reported a patient with a pyocle in which the fronto-ethmoid cell complex was cured by an external and internal nasal drainage procedure.

Ogston (2) in 1884 advocated trephining of the frontal sinuses for catarrhal diseases unresponsive to medical therapy. He used a midline vertical incision, elevated the periosteum, entered the sinus with a sixpenny size trephine crown, and enlarged the opening with a chisel. Diseased mucous membrane was removed, and a drainage tube was placed into the nose. Three patients described were asymptomatic for a considerable period of time.

Obiteration of the frontal sinus performed by Kuhnt (3) in 1895 included removal of the anterior wall, sparing 0.5 cm above the orbital margin. He cited Ringe as performing a similar operation 150 years earlier and quoted techniques of his contemporaries, Heibinger & Jan-

sen, who recommended intranasal drainage. Kuhnt, however, favored external drainage alone and daily postoperative irrigations of the cavity with sublimate.

Röpke (4) in 1898 modified the procedure by removing the anterior, inferior and medial walls of the frontal sinus to expose adequately involved ethmoid cells. Riedel (5) stressed the importance of taking the inferior sinus wall.

The osteoplastic anterior wall approach to the frontal sinus was described by Schönborn (6) in 1894. Brägger (7), in 1895 reported upon the use of a skin-periosteum-bone flap which was successfully removed and reimplanted. In 1904 Winckler (8) suggested an osteoplastic procedure with the flap hinged above the orbital margin. He used this approach only when no bone or soft tissue was involved by disease and when no intracranial complications were suspected. Beck (9) and

Hoffman (10) later made further minor alterations of the osteoplasty

After the turn of the century Killian (11) proposed a frontal sinus operation which included removal of the anterior and inferior walls except for a bridge of bone in the supra orbital area. Later he included the frontal process of the maxilla in his dissection to facilitate ethmoid cell exposure and establish a wide opening into the nose. Ethmoid cells were exenterated and a flap of nasal mucosa was formed to maintain an open communication with the denuded frontal sinus. Lothrop (12) suggested circumventing the nasofrontal duct on the diseased side by removal of the intersinus septum and utilization of the opposite nasofrontal duct for drainage.

The operation originally proposed by Jansen (13) in 1902 and later modified by Lynch (14) in 1921 was considered the procedure of choice for the next several decades. This procedure consisted of removal of the frontal sinus floor, preservation of the anterior wall and exenteration of the adjoining ethmosphenoid cell system. Lynch advocated the removal of every vestige of frontal sinus mucosa, and the concurrent treatment of any intranasal obstruction or antral disease. Ritter (15) modified the Jansen technique by elevating the anterior sinus wall laterally as a flap.

These extensive surgical procedures often did not eliminate disease and the search continued for better therapy for frontal sinusitis. Skillern (16) advocated a conservative approach to sinus surgery at this time. Smith (17) used a Thiersch skin graft around a rubber tube to maintain the patency of the nasofrontal duct

and reported occlusion in only 3 of 100 patients. Sewall (18), McNaught (19), Boyde (20) and Ogura (21) published reports upon methods of reconstruction of the nasofrontal duct with adjoining mucoperiosteal flaps, a Killian (11) had originally suggested.

The use of prosthetic devices to maintain the patency of the nasofrontal duct also had proponents. Ingals (22) originally had devised a gold tube, and Goodale (23) suggested tantalum, but Hugenberg & Williams (24) reported a foreign body reaction to it. Erich & New (25) used an acrylic obturator with success.

Lillie & Williams (26) preserved the frontal process of the maxilla to prevent soft tissue contracture of the nasofrontal opening.

Subsequently in view of the continued high rate of recurrent disease with previous procedures, Gibson & Walker (27), MacBeth (28), Tato, Sibbald & Bergaglio (29), Bergara & Itoiz (30) and Goodale & Montgomery (31) utilized the osteoplastic flap approach and reported favorable results. Then in 1964 Goodale & Montgomery (32, 33) combined the osteoplastic flap and the obliteration of the sinus with a fat graft. Sanders (34) stressed the importance of a thorough removal of sinus mucosa accomplished through the floor of the frontal sinus rather than by the osteoplastic flap.

In 1967 Kirchner, Toledo & Robison (35) described a modification of the osteoplastic flap to facilitate removal of lesions of the orbit as well as the frontal sinus and frontal bone. Failla (36) recently recommended suture of the mucosa at the nasofrontal duct level in ablations following frontal sinus fracture.

III Surgical Anatomy

The frontal sinus (37) is an outgrowth of the frontal recess in the cephalo-ventral end of the middle turbinate where frontal furrows or pits evaginate to form the frontal cells. It begins to invade the frontal bone in the second year of

life but complete development is not reached until about the sixteenth year. Consequently it does not have clinical significance until approximately this time.

The prominence of the brow is no indica-

tion of the size of the sinuses. They are rarely symmetrical and vary in depth and shape as well. Each cavity is partially divided by horizontal and vertical septa. The capacity varies from 1 to 44 cm³ and the intersinus septum is usually complete. A larger frontal sinus may occupy both frontal regions, and the smaller one may lie anterior or posterior to it. Agnensis of the frontal sinus is a rare anomaly but duplication and triplication is common. Congenital deficiencies in the osseous walls, especially in the orbital portion, do occur (38) and the importance of these defects in regard to the spread of infection to the orbit or meninges is apparent.

Booy septa frequently project inward from the walls of the frontal sinus and divide it incompletely into compartments. These projections must be leveled during surgery to assure complete removal of mucous membrane.

Orbital and temporal recesses may be extensive. Whitnall (39) described a frontal sinus which undermined the orbital roof to the apex. These recesses are sometimes ignored and considered a cause for surgical failure.

The squama of the frontal bone is very thick and has diploic tissue with marrow between two compact laminae, but the orbital portion is thin and composed only of compact bone. Thus the anterior wall of the frontal sinus is thick like the squama, and the floor and posterior wall are thin. The floor is the site of the earliest external sign of inflammation in acute suppurative sinusitis, and it is also the preferred area for entering the sinus, being most dependent and containing no diploic bone. The anatomic landmark for surgical intervention is the junction of the articulation of the nasal bone (frontal process of the maxilla) and the frontal bone.

After the sinus is entered, one must be cautious with direction over the dorsomedial wall for the olfactory fissure occasionally projects into the sinus as a bulla in this area. Another area of concern is the posterior wall of the nasofrontal duct beneath which the anterior edge of the cribriform plate lies. Frequently a

bulge into the lower lumen of the sinus is caused by a frontal bullar cell, and occasionally a nest of cells may be present in this area.

The position of the ostium in the floor is of practical importance for when the isthmus is posteriorly placed the pathway into the nose is tortuous with encroachment by frontal recess or infundibular cells, but when it lies anteriorly the pathway is vertically direct into the anterior middle meatus (40). It has been stated that the duct leads into the frontal recess in 67% of patients, the ethmoidal infundibulum in 30% and an ethmoidal cell expansion in 3% (41). A narrow middle meatus from a cellular or hypertrophied middle turbinate may also compromise the nasal drainage route.

The mucous membrane of the frontal sinuses is composed of a stratified ciliated columnar epithelium overlying a delicate basal membrane and thin tunica propria (42, 43). Although continuous with the nasal fossa, it is much thinner and contains fewer glands and elastic fibers. Numerous arteries and veins lie in the stroma. The tunica is firmly adherent to the underlying perosteum, making dissection of the mucoperiosteum a necessity when removing the membrane during surgery.

The arterial blood supply to the frontal sinus is the anterior and posterior ethmoidal branches of the ophthalmic artery. Ramifications of these vessels form a close plexiform network in the mucous membrane. Veins also form a plexus and end in the superior ophthalmic vein although a few may communicate intracranially through the diploic system, foramina in the cribriform plate, or through a patent foramen cecum. These anastomoses have obvious significance in the pathogenesis of intracranial complications resulting from frontal sinusitis.

A lymphatic network varies with the thickness of the tunica propria and communicates with the nasal cavity in dorsal and ventral groups of collecting vessels (44). The ventral group empties into the facial and submandibular nodes and the dorsal group terminates in the deep cervical or retropharyngeal nodes.

Hoffman (10) later made further minor alterations of the osteoplasty

After the turn of the century Killian (11) proposed a frontal sinus operation which included removal of the anterior and inferior walls except for a bridge of bone in the supra-orbital area. Later he included the frontal process of the maxilla in his dissection to facilitate ethmoid cell exposure and establish a wide opening into the nose. Ethmoid cells were everted and a flap of nasal mucosa was formed to maintain an open communication with the denuded frontal sinus. Lothrop (12) suggested circumventing the nasofrontal duct on the diseased side by removal of the intersinus septum and utilization of the opposite nasofrontal duct for drainage.

The operation originally proposed by Jansen (13) in 1902, and later modified by Lynch (14) in 1921, was considered the procedure of choice for the next several decades. This procedure consisted of removal of the frontal sinus floor, preservation of the anterior wall, and exenteration of the adjoining ethmoidal cell system. Lynch advocated the removal of every vestige of frontal sinus mucosa and the concurrent treatment of any intranasal obstruction or antral disease. Rutter (15) modified the Jansen technique by elevating the anterior sinus wall laterally as a flap.

These extensive surgical procedures often did not eliminate disease and the search continued for better therapy for frontal sinusitis. Skillern (16) advocated a conservative approach to sinus surgery at this time. Smith (17) used a Thiersch skin graft around a rubber tube to maintain the patency of the nasofrontal duct

and reported occlusion in only 3 of 100 patients. Sewall (18), McNaught (19), Boyder (20) and Ogura (21) published reports upon methods of reconstruction of the nasofrontal duct with adjoining mucoperiosteal flaps, as Killian (11) had originally suggested.

The use of prosthetic devices to maintain the patency of the nasofrontal duct also had proponents. Ingals (22) originally had devised a gold tube and Goodale (23) suggested tantalum, but Hugenberg & Williams (24) reported a foreign body reaction to it. Erich & New (25) used an acrylic obturator with success.

Lillie & Williams (26) preserved the frontal process of the maxilla to prevent soft tissue contracture of the nasofrontal opening.

Subsequently, in view of the continued high rate of recurrent disease with previous procedures, Gibson & Walker (27), MacBeth (28), Tato, Sibbald & Bergaglio (29), Bergam & Itoiz (30) and Goodale & Montgomery (31) utilized the osteoplastic flap approach and reported favorable results. Then in 1964, Goodale & Montgomery (32, 33) combined the osteoplastic flap and the obliteration of the sinus with a fat graft. Sanders (34) stressed the importance of a thorough removal of sinus mucosa accomplished through the floor of the frontal sinus rather than by the osteoplastic flap.

In 1967, Kirchner, Toledo & Robson (35) described a modification of the osteoplastic flap to facilitate removal of lesions of the orbit as well as the frontal sinus and frontal bone. Failla (36) recently recommended suture of the mucosa at the nasofrontal duct level in ablations following frontal sinus fracture.

III Surgical Anatomy

The frontal sinus (37) is an outgrowth of the frontal recess in the cephalo-ventral end of the middle turbinate where frontal furrows or pits evaginate to form the frontal cells. It begins to invade the frontal bone in the second year of

life but complete development is not reached until about the sixteenth year. Consequently it does not have clinical significance until approximately this time.

The prominence of the brow is no indica-

tion of the size of the sinuses. They are rarely symmetrical and vary in depth and shape as well. Each cavity is partially divided by horizontal and vertical septa. The capacity varies from 1 to 44 cm³ and the intersinus septum is usually complete. A larger frontal sinus may occupy both frontal recesses, and the smaller one may lie anterior or posterior to it. Agenesis of the frontal sinus is a rare anomaly but duplication and triplication is common. Congenital dehiscences in the osseous walls, especially in the orbital portion, do occur (38) and the importance of these defects in regard to the spread of infection to the orbit or meninges is apparent.

Bony septa frequently project inward from the walls of the frontal sinus and divide it incompletely into compartments. These projections must be leveled during surgery to assure complete removal of mucous membrane.

Orbital and temporal recesses may be extensive. Whitwell (39) described a frontal sinus which undermined the orbital roof to the apex. These recesses are sometimes ignored and considered a cause for surgical failure.

The squama of the frontal bone is very thick and has diploic tissue with marrow between two compact laminae, but the orbital portion is thin and composed only of compact bone. Thus the anterior wall of the frontal sinus is thick like the squama, and the floor and posterior wall are thin. The floor is the site of the earliest external sign of inflammation in acute suppurative sinusitis, and it is also the preferred area for entering the sinus, being most dependent and containing no diploic bone. The anatomic landmark for surgical intervention is the junction of the articulation of the nasal bone frontal process of the maxilla and the frontal bone.

After the sinus is entered, one must be cautious with dissection over the dorsomedial wall for the olfactory fissure occasionally projects into the sinus as a bulla in this area. Another area of concern is the posterior wall of the nasofrontal duct beneath which the anterior edge of the cribriform plate lies. Frequently a

bulge into the lower lumen of the sinus is caused by a frontal bullar cell, and occasionally a nest of cells may be present in this area.

The position of the ostium in the floor is of practical importance for when the isthmus is posteriorly placed the pathway into the nose is tortuous with encroachment by frontal recess or infundibular cells, but when it lies anteriorly the pathway is vertically direct into the anterior middle meatus (40). It has been stated that the duct leads into the frontal recess in 67% of patients, the ethmoidal infundibulum in 30% and an ethmoidal cell expansion in 3% (41). A narrow middle meatus from a cellular or hypertrophied middle turbinate may also compromise the nasal drainage route.

In 1967 Kirchner, Toledo & Robinson (35) described a modification of the osteoplastic flap to facilitate removal of lesions of the orbit as well as the frontal sinus and frontal bone. Fallia (36) recently recommended suture of the mucosa at the nasofrontal duct level in ablations following frontal sinus fracture.

III Surgical Anatomy

The frontal sinus (37) is an outgrowth of the frontal recess in the cephalo-ventral end of the middle turbinate where frontal furrows or pits evaginate to form the frontal cells. It begins to invade the frontal bone in the second year of

life, but complete development is not reached until about the sixteenth year. Consequently it does not have clinical significance until approximately this time.

The prominence of the brow is no indica-

medially. The axis of the ethmoid labyrinth intersects with the optic canal, and this is the site where the optic nerve is likely to be injured. Also the roof, medial, and lateral walls of the canal may be thinned out by extensions

of the sphenoid or posterior ethmoid cells further predisposing the nerve to injury during surgery. Westlake (45) first reported this relationship in 1923.

IV Physiologic Principles

McDonald (46) and Heisterich (47) observed the nasal efficiency in filtration, heating and humidification of inspired air. These functions are impaired when vasomotor control is interrupted by exposure and viral invasion. There is an ischemia of the mucous membrane with a deficient mucus blanket and ciliary action. The resulting obstruction to aeration and discharge predisposes to bacterial invasion and the production of a suppurative sinusitis.

The ciliated mucous membrane with its secreting glands and overlying blanket of mucus must be regarded as a membrane of defense capable of returning to a normal state under favorable conditions (48, 49).

Hilding (49) has demonstrated that the mucus blanket is propelled by the cilia in a very consistent spiral direction around the sinus to discharge through the nasofrontal duct into the nose. The force is considered optimal at 5 g/cm² with the weight load increasing the activity of the cilia. The speed of the cilia in man is about 250 cycles per minute with the motion of the blanket and force becoming greater as the ostium is approached (50).

The ostium and its surrounding pathway into the nose must remain patent for normal aeration and ciliary function. Positive intranasal atmospheric pressure with an occluded nasofrontal duct will prevent discharge of sinus contents by gravity. Hence if aeration can be established by conservative means, drainage is facilitated by ciliary action, and the infection may be eradicated. Local and systemic medical therapy will accomplish these objectives in most acute diseases. However at times in subacute or early chronic sinusitis, minor surgical pro-

cedures are also indicated. The goal is to establish drainage with minimal trauma to the nasofrontal duct area.

Excessive or prolonged use of local decongestants may produce a superimposed rhinitis medicamentosa. Lillie (51) observed the congestion of the nasal mucosa after prolonged irrigations at surgery and Stark (52) demonstrated the destructive histologic changes in rabbits after irrigations with tap water, saline, and 2% sodium chloride. Epithelial cells were distended and cilia were absent. The mucus layer and tunica were infiltrated with polymorphonuclear cells and the blood vessels were dilated. Injury may also be induced by nasal packing and instrumentation with erosion or avulsion of inflamed nasal mucosa.

Formerly surgery upon the frontal sinus was followed by a high incidence of recurrent disease. In an attempt to discover the causes of surgical failure, Hilding (53) removed the intersinus septum and strips of mucous membrane from the frontal sinuses of dogs and found that high ridges and diaphragms of scar tissue formed at the excision sites. In another series of experiments designed to determine the nature of regenerated mucous membrane Hilding (53) found that in complete removal the sinus often filled with scar tissue and in partial removal an abortive cystic epithelial lining reformed. These findings differ from those of Coates & Erner (55) who previously had noted complete regeneration in one dog after radical removal of the mucous membrane. McGregor (56) reported on a human specimen with normal lining of the frontal sinus six months after operation. Walsh (57) in further

The general sensory nerve supply to the frontal sinus is the anterior ethmoidal nerve, a branch of the ophthalmic division of the trigeminal nerve. Autonomic innervation is by parasympathetic fibers from the sphenopalatine ganglion and sympathetic fibers from the carotid plexus.

Not infrequently ethmoidectomy may accompany frontal sinus surgery and several anatomic landmarks should be stressed. Attachments of the middle and superior turbinates form the medial boundary of the ethmoid labyrinth. The cribriform plate is located medially and preservation of the turbinates protects it. The lamina papyracea of the medial orbital wall forms the lateral boundary. Anterior and posterior ethmoidal vessels are encountered along the junction of the superior and medial orbital wall.

Structures of the medial orbital wall lie in close proximity to the fronto-ethmoid incision, and a discussion of anatomical landmarks in this area is warranted. The septum orbitale is a thin membrane of connective tissue which extends from the orbital to the palpebral margins and forms a barrier between the lids and orbital contents. A frontal incision placed too low will perforate this partition and orbital fat will herniate through the opening.

The medial palpebral ligament is palpable as a horizontal cord like band of connective tissue connecting the tarsal to the lacrimal crest. It lies in front of the upper half of the lacrimal sac, and its proximity to the fronto-ethmoid incision should be recognized.

The lacrimal canaliculi are two minute canals connecting the lacrimal puncta to the lacrimal sac. They are each 10 mm long with a short vertical part deep to the puncta and a longer horizontal part running along the medial upper and lower lid margins. An incision placed along the orbital rim will avoid these structures.

The lacrimal sac lies beneath the periorbital in the lacrimal fossa on the medial margin of the orbit. The nasolacrimal duct is a continuation of the sac lying in the osseous nasolacrimal canal

and opening into the inferior meatus of the nose. The fundus of the lacrimal sac is often seen in the lower part of the incision just anterior to the posterior lacrimal crest. This crest forms the anterior limit of the external ethmoidectomy. Proceeding forward on the medial side of the upper half of the lacrimal fossa one will encounter one or two cells of the anterior ethmoid group known as the lacrimoethmoidal cells (39). Although the anterior ethmoidal cells may be approached externally through this route the operation should be completed through the intranasal approach.

The fovea trochlearis is a small round pit in the bone at the anteromedial angle of the roof of the orbit about 5 mm from the margin. The trochlea or pulley of the superior oblique muscle is a finely grooved, curved plate of fibrocartilage about 4 mm long and 6 mm broad. The edges are attached to the fovea by fibrous tissue completing the tube through which the superior oblique tendon slides. If the frontal periosteum is reapproximated after the bone removal, no impairment of extraocular muscle function will result. The trochlea attached to periosteum is restored to its normal position.

The inferior oblique muscle originates from a shallow depression on the inferior medial orbital wall just lateral to the opening of the nasolacrimal canal. It passes laterally and posteriorly into the orbit as a flat band beneath the inferior rectus and inserts into the posterolateral hemisphere of the eyeball. The proximity of this muscle to the ethmoidal cells in this area should be recognized.

At the apex of the orbit the optic nerve is covered by the dural sheath and closely surrounded by the recti muscles at their origin from the annulus of Zinn. The ophthalmic artery lies on the lateral aspect of the nerve posteriorly at the apex.

The optic foramen is located at the apex of the roof of the orbit and opens into the optic canal formed by the two roots of the lesser wing of the sphenoid bone. It is 4-9 mm in length and its axis is directed posteriorly and

and the bony opening was occluded with bone chips or surrounding soft tissue. The cavity was left to be spontaneously obliterated in nine cases. Abdominal fat was inserted in one highly pneumatized cavity.

F COMPLICATIONS

The majority of complications encountered in this series were ocular (Table VIII). Supra-orbital nerve injury occurred in three patients during exposure of highly pneumatized frontal sinuses. Anesthesia was temporary in two patients where the nerve was compressed by retractors and permanent in one patient where the nerve was divided.

Superior oblique palsy complicated one fronto-ethmoid exenteration. The trochlea was displaced from its fossa and not replaced. Impaired function was permanent and required a resection of the inferior oblique muscle.

Recently we encountered an inferior oblique muscle paralysis following a fronto-ethmoid exenteration. The resulting hypotropia and vertical diplopia subsided within three months.

Optic neuritis occurred in one patient following a fronto-ethmoid exenteration. Recovery occurred within two months. It is probable that the optic nerve was confused by retraction during the posterior ethmoidectomy.

The fundus of the lacrimal sac was lacerated in one patient. The defect was sutured, and there was no epiphora.

Cerebrospinal fluid rhinorrhea occurred postoperatively in one patient who had recurrent basal cell carcinoma of the inner eyelid which extended into the nose, ethmoid, and frontal sinuses. The posterior frontal sinus wall was eroded and tumor invaded the dura. No leak was noted at surgery but after two weeks of radiation therapy a rhinorrhea occurred. Specific diagnosis was made by chemical analysis. The fistula closed spontaneously in five days.

Meningitis occurred postoperatively in one patient where the posterior sinus plate had

Table VIII Complications

Cerebrospinal fluid rhinorrhea	1

been eroded and granulations were covering the dura. No specific organism was cultured from the spinal fluid, although *Staphylococcus aureus* had previously been isolated from the nose. The patient responded well to massive antibiotic therapy.

One patient with a frontal lobe abscess most likely had the abscess prior to sinus surgery for it appeared chronic upon neurosurgical intervention two weeks later. We have encountered the reverse situation where asymptomatic frontal sinusitis was discovered by the neurosurgeon during operation for a symptomatic frontal lobe abscess.

G RECURRENCE RATE

Most recurrences were associated with the minor procedures of incision, drainage and trephine. Reconstructions of the nasofrontal duct were complete failures in our series. Extended trephine and nasofrontal duct stenting procedures reduced the recurrence rate by nearly 50%. The obliteration, however, has been a highly successful operation with no recurrences in date.

All patients were followed closely for at least one year after surgery. Recurrent or continued disease usually manifested itself within that period of time. One exception was one patient with a latent period of 15 years. For the obliteration procedure the minimum follow-up time was six months and the maximum time was six years.

The general sensory nerve supply to the frontal sinus is the anterior ethmoidal nerve, a branch of the ophthalmic division of the trigeminal nerve. Autonomic innervation is by parasympathetic fibers from the sphenopalatine ganglion and sympathetic fibers from the carotid plexus.

Not infrequently ethmoidectomy may accompany frontal sinus surgery and several anatomic landmarks should be stressed. Attachments of the middle and superior turbinates form the medial boundary of the ethmoid labyrinth. The cribriform plate is located medially and preservation of the turbinates protects it. The lamina papyracea of the medial orbital wall forms the lateral boundary. Anterior and posterior ethmoidal vessels are encountered along the junction of the superior and medial orbital wall.

Structures of the medial orbital wall lie in close proximity to the fronto-ethmoid incision, and a discussion of anatomical landmarks in this area is warranted. The septum orbitale is a thin membrane of connective tissue which extends from the orbital to the palpebral margins and forms a barrier between the lids and orbital contents. A frontal incision placed too low will perforate this partition and orbital fat will herniate through the opening.

The medial palpebral ligament is palpable as a horizontal cord-like band of connective tissue connecting the tarsi to the lacrimal crest. It lies in front of the upper half of the lacrimal sac and its proximity to the fronto-ethmoid incision should be recognized.

The lacrimal canaliculi are two minute canals connecting the lacrimal puncta to the lacrimal sac. They are each 10 mm long with a short vertical part deep to the puncta and a longer horizontal part running along the medial upper and lower lid margins. An incision placed along the orbital rim will avoid these structures.

The lacrimal sac lies beneath the periorbita in the lacrimal fossa on the medial margin of the orbit. The nasolacrimal duct is a continuation of the sac lying in the osseous nasolacrimal canal

and opening into the inferior meatus of the nose. The fundus of the lacrimal sac is often seen in the lower part of the incision just anterior to the posterior lacrimal crest. This crest forms the anterior limit of the external ethmoidectomy. Proceeding forward on the medial side of the upper half of the lacrimal fossa one will encounter one or two cells of the anterior ethmoid group known as the lacrimoethmoidal cells (39). Although the anterior ethmoidal cells may be approached externally through this route the operation should be completed through the intranasal approach.

The fovea trochlearis is a small round pit in the bone at the anteromedial angle of the roof of the orbit about 5 mm from the margin. The trochlea or pulley of the superior oblique muscle is a finely grooved curved plate of fibrocartilage about 4 mm long and 6 mm broad. The edges are attached to the fovea by fibrous tissue completing the tube through which the superior oblique tendon slides. If the frontal periosteum is reapproximated after the bone removal no impairment of extraocular muscle function will result. The trochlea attached to periosteum is restored to its normal position.

and sequestration often were not discernible. The only specific mucosal change noted was a fluid level. All four patients with malignant tumors manifested specific mucosal and bone changes.

Nonspecific changes such as increased density of the sinus lumen, loss of the mucoperiosteal line and scleroses around the margins were frequently noted.

When radiopaque dye could be instilled into the frontal sinuses, diffuse mucosal hypertrophy could be demonstrated. However the technical difficulties encountered with an occluded middle meatus and rapid return of the dye into the nose limited the value of this procedure.

Tomography and more recently polytomography demonstrated mucosal changes and bone dehiscence not apparent with conventional views.

C BACTERIOLOGY

Most patients had received antibiotic therapy prior to surgical intervention. Exudate was obtained from the anterior middle meatus when spontaneous drainage occurred or from the sinus lumen during surgery (Table IV).

Staphylococcus aureus was the predominant organism isolated, and the *Diplococcus pneu-*

moniae was second in frequency. *Alpha Streptococcus* and *Proteus vulgaris* were cultured on three occasions, but their pathogenicity is doubted. In four patients no organisms were found. *Streptococcus hemolyticus*, often considered a pathogen in frontal sinusitis, was not found in this series.

D PATHOLOGY

Predominant mucosal changes were representative of the stage of the disease at which surgery was performed (Table V). Acute diffuse and localized suppuration were found in two-thirds of the specimens and diffuse chronic hypertrophic suppuration and mucocoeles were present in the other third.

Bone pathology noted in half of the patients included osteoporosis with dehiscence of the frontal floor and osteitis with increased bone density. Both changes occurred simultaneously in patients with chronic disease (Table VI). Only two cases of osteomyelitis were seen, and in each the process was localized in the anterior wall and was arrested by limited bone removal. No localized abscesses, draining sinuses or sequestered bone, so characteristic of osteomyelitis elsewhere were encountered.

The cell types in the four malignant tumors were squamous cell (2), reticulum cell (1) and basal cell (1). Considerable inflammatory reac-

experiments on dogs demonstrated rapid regeneration of normal mucosa throughout the sinus when only the lining of the nasofrontal duct was preserved. Although inconclusive, these various observations tend to support the ability of the frontal sinus mucosa to regenerate and call for a conservative approach to surgical therapy in acute, subacute and early phases of chronic disease.

When more radical surgery is indicated, Van Alyea (41) has cautioned against procedures which direct air streams into the ostia or sinus cavities. Disruption of intranasal anatomy and

physiology is clearly demonstrated by the crusting, atrophy and ulceration often apparent at the site of an intranasal ethmoidectomy or turbinate resection. These patients may have more symptoms related to the surgery than to the primary disease. The extranasal approach to the fronto-ethmoid sinuses therefore appears more logical since important normal intranasal function is maintained. Also the irreversibly damaged sinuses can be exenterated and partially separated from the nasal cavity by this procedure.

V Review of Cases

Records of 33 patients operated upon between 1946 and 1968 were reviewed (Table I). Inflammation was present in 31. Two cases of osteomas were not secondarily infected. Four patients had malignant neoplasms. Three tumors presented intranasally and involved the ethmoid and frontal sinuses. The fourth tumor was a basal cell carcinoma of the skin adjacent to the inner canthus of the eye lids which eroded the bone of the lateral nasal wall and extended into the ethmoid and frontal sinuses. There was evidence of suppuration with all of the tumors.

In the series there were 26 males and 5 females and the age range varied between 18 and 66. The predominant veteran population explains this distribution.

A ETIOLOGY

Local etiologic factors considered contributory to the development of frontal sinusitis are difficult to evaluate (Table II). A significant ob-

structive deviation of the nasal septum was present in 25% of cases. Hypertrophied anterior middle turbinates and anterior middle mental polyps were found in 20%. Frontal sinus fracture appeared to be a significant predisposing factor in 33% of this series. Associated maxillary and ethmoid sinusitis was found in half of the patients. However, definitive treatment of the maxillary or ethmoid sinusitis did not seem to influence the clinical course of the frontal sinus disease. Specific allergic etiology demonstrated by nasal eosinophilia, positive skin testing and favorable response to desensitization was found in less than 10% of patients. No local etiologic factors could be determined in 20%.

B RADIOLOGY

Frontal projections of Caldwell & Waters were of value in demonstrating sinus size configuration, and presence of supraorbital ethmoid or frontal bullar cells. Varying degrees of opacification were noted, but definite indications of activity of the disease process were present in only half of the patients (Table III).

Discrete bony changes such as erosion of the sinus floor and anterior plate or mottling

tion surrounded the neoplastic cells and several biopsies were necessary to establish a histologic diagnosis. The neoplasms grossly presented as granular polypoid or ulcerative lesions.

E. SURGERY

Indications for surgery were lack of response to medical therapy, persistent localizing signs, or signs of impending intracranial complications.

Operative procedures included incision and drainage, simple or extended trephination and obliteration by osteoplastic flap or frontal floor approach (Table VII).

Incision and drainage was performed on three patients. One with an initial attack of frontal sinusitis had a subperiosteal abscess with no gross evidence of bone erosion. The other two cases with secondary attacks, had mucocoele formation and erosion of the sinus floor.

Trephination was considered the primary procedure for acute eroding sinusitis whenever drainage was necessary. Many of our cases fell into this category with multiple procedures performed in some patients.

Extended trephination was also performed frequently when reoperation was indicated. An opening in the frontal sinus floor was enlarged to adequately inspect the mucosal lining and the posterior sinus plate. Hyperplastic and polypoid mucosa was removed but a cuff was usually spared at the nasofrontal duct orifice. Margins of eroded bone of the floor, anterior or posterior wall, were removed until normal appearance and consistency were apparent. Granulations were removed from the dura beneath a desiccated posterior plate in two patients.

Several attempts were made at reconstruction of the nasofrontal duct, with mucosal and skin grafts. These patients formed strictures and had recurrent frontal sinusitis.

Polyethylene and silastic tubes were utilized as stents in the nasofrontal duct in seven patients. The initial experience was encouraging but recurrent disease was frequent.

Sinusotomy in the four patients with malignant tumors was considered a diagnostic and therapeutic procedure. Extent of the disease was determined and all the gross tumor was removed. A widely patent intranasal communication was established to facilitate drainage during postoperative radiation therapy.

Obliteration was performed only in the quiescent or chronic stage of disease. The osteoplastic flap was used in the first two patients, but the frontal floor approach was used for the subsequent eight. Mucosa and bony septa were meticulously removed from the sinus lumen. The cuff of mucosa in the nasofrontal duct was excised well into the nose.

Table VII Operations

Procedure	No. cases	Recurrence rate

(Follow-up time—6 months to 20 years)

and the bony opening was occluded with bone chips or surrounding soft tissue. The cavity was left to be spontaneously obliterated in nine cases. Abdominal fat was inserted in one highly pneumatized cavity.

F COMPLICATIONS

The majority of complications encountered in this series were ocular (Table VIII). Supra-orbital nerve injury occurred in three patients during exposure of highly pneumatized frontal sinuses. Anesthesia was temporary in two patients where the nerve was compressed by retractors and permanent in one patient where the nerve was divided.

Superior oblique palsy complicated one fronto-ethmoid exenteration. The trochlea was displaced from its fossa and not replaced. Impaired function was permanent and required a resection of the inferior oblique muscle.

Recently we encountered an inferior oblique muscle paralysis following a fronto-ethmoid exenteration. The resulting hypotropia and vertical diplopia subsided within three months.

Optic neuritis occurred in one patient following a fronto-ethmoid exenteration. Recovery occurred within two months. It is probable that the optic nerve was contused by retraction during the posterior ethmoidectomy.

The fundus of the lacrimal sac was lacerated in one patient. The defect was sutured, and there was no epiphora.

Cerebrospinal fluid rhinorrhea occurred postoperatively in one patient who had recurrent basal cell carcinoma of the lower eyelid which extended into the nose, ethmoid, and frontal sinuses. The posterior frontal sinus wall was eroded and tumor invaded the dura. No leak was noted at surgery but after two weeks of radiation therapy a rhinorrhea occurred. Specific diagnosis was made by chemical analysis. The fistula closed spontaneously in five days.

Meningitis occurred postoperatively in one patient where the posterior sinus plate had

The fundus of the lacrimal sac was lacerated in one patient. The defect was sutured, and there was no epiphora.

Cerebrospinal fluid rhinorrhea occurred postoperatively in one patient who had recurrent basal cell carcinoma of the lower eyelid which extended into the nose, ethmoid, and frontal sinuses. The posterior frontal sinus wall was eroded and tumor invaded the dura. No leak was noted at surgery but after two weeks of radiation therapy a rhinorrhea occurred. Specific diagnosis was made by chemical analysis. The fistula closed spontaneously in five days.

Meningitis occurred postoperatively in one patient where the posterior sinus plate had

been eroded and granulations were covering the dura. No specific organism was cultured from the spinal fluid, although *Staphylococcus aureus* had previously been isolated from the nose. The patient responded well to massive antibiotic therapy.

One patient with a frontal lobe abscess most likely had the abscess prior to sinus surgery for it appeared chronic upon neurosurgical intervention two weeks later. We have encountered the reverse situation where asymptomatic frontal sinusitis was discovered by the neurosurgeon during operation for a symptomatic frontal lobe abscess.

G RECURRENCE RATE

Most recurrences were associated with the minor procedures of incision, drainage and trephine. Reconstructions of the nasofrontal duct were complete failures in our series. Extended trephine and nasofrontal duct stenting procedures reduced the recurrence rate by nearly 50%. The obliteration, however, has been a highly successful operation with no recurrences to date.

All patients were followed closely for at least one year after surgery. Recurrent or continued disease usually manifested itself within that period of time. One exception was one patient with a latent period of 15 years. For the obliteration procedure the minimum follow-up time was six months and the maximum time was six years.

tion surrounded the neoplastic cells and several biopsies were necessary to establish a histologic diagnosis. The neoplasms grossly presented as granular polypoid or ulcerative lesions.

E SURGERY

Indications for surgery were lack of response to medical therapy, persistent localizing signs, or signs of impending intracranial complications.

Operative procedures included incision and drainage, simple or extended trephination, and obliteration by osteoplastic flap or frontal floor approach (Table VII).

Incision and drainage was performed on three patients. One with an initial attack of frontal sinusitis had a subperiosteal abscess with no gross evidence of bone erosion. The other two cases, with secondary attacks, had mucocoele formation and erosion of the sinus floor.

Trephination was considered the primary procedure for acute eroding sinusitis whenever drainage was necessary. Many of our cases fell into this category with multiple procedures performed in some patients.

Extended trephination was also performed frequently when reoperation was indicated. An opening in the frontal sinus floor was enlarged to adequately inspect the mucosal lining and the posterior sinus plate. Hyperplastic and polypoid mucosa was removed, but a cuff was usually spared at the nasofrontal duct orifice. Margins of eroded bone of the floor, anterior or posterior wall, were removed until normal appearance and consistency were apparent. Granulations were removed from the dura beneath a dehiscence posterior plate in two patients.

Several attempts were made at reconstruction of the nasofrontal duct with mucosal and skin grafts. These patients formed strictures and had recurrent frontal sinusitis.

Polyethylene and silastic tubes were utilized as stents in the nasofrontal duct in seven patients. The initial experience was encouraging but recurrent disease was frequent.

Sinusotomy in the four patients with malignant tumors was considered a diagnostic and therapeutic procedure. Extent of the disease was determined and all the gross tumor was removed. A widely patent intranasal communication was established to facilitate drainage during postoperative radiation therapy.

Obliteration was performed only in the quiescent or chronic stage of disease. The osteoplastic flap was used in the first two patients, but the frontal floor approach was used for the subsequent eight. Mucosa and bony septa were meticulously removed from the sinus lumen. The cuff of mucosa in the nasofrontal duct was excised well into the nose.

and the bony opening was occluded with bone chips or surrounding soft tissue. The cavity was left to be spontaneously obliterated in nine cases. Abdominal fat was inserted in one highly pneumatized cavity.

F COMPLICATIONS

The majority of complications encountered in this series were ocular (Table VIII). Supra-orbital nerve injury occurred in three patients during exposure of highly pneumatized frontal sinuses. Anesthesia was temporary in two patients where the nerve was compressed by retractors and permanent in one patient where the nerve was divided.

Superior oblique palsy complicated one fronto-ethmoid exenteration. The trochlea was displaced from its fossa and not replaced. Impaired function was permanent and required a resection of the inferior oblique muscle.

Recently we encountered an inferior oblique muscle paralysis following a fronto-ethmoid exenteration. The resulting hypotropia and vertical diplopia subsided within three months.

Optic neuritis occurred in one patient following a fronto-ethmoid exenteration. Recovery occurred within two months. It is probable that the optic nerve was contused by retraction during the posterior ethmoidectomy.

The fundus of the lacrimal sac was lacerated in one patient. The defect was sutured, and there was no epiphora.

Cerebrospinal fluid rhinorrhea occurred postoperatively in one patient who had recurrent basal cell carcinoma of the inner eyelid which extended into the nose, ethmoid, and frontal sinuses. VI Discussion

Frontal sinusitis is infrequent today. The lower incidence of this disease as compared with maxillary sinusitis may be due to the natural dependent drainage. Also, antibiotic therapy has reduced the incidence of acute complicated sinusitis and allowed limited operations to be performed in the chronic phase of the disease (58). However, with the less accurate and technically more difficult means of establishing a diagnosis of frontal sinusitis by irrigation and Proetz displacement therapy, it is surmised that there are many cases of quiescent chronic suppurative disease that are overlooked. Reluctance to operate because of the previous high recurrence and complication rates may also explain the infrequent reports in the literature.

Significant etiologic factors suggested in our series were frontal sinus fractures, and co-existing maxillary and ethmoid sinus disease. Morrison (59) previously pointed out that chronic frontal sinusitis seldom occurs as a single clinical entity unless caused by trauma. Work (60-61) also noted this relationship to trauma.

Conventional radiologic projections of Caldwell & Waters revealed general configuration, opacity of sinus lumen, and sclerosis of bony walls. Polytomography has aided in diagnosis of activity with visualization of the details of mucosal thickening and bone erosion. In most of the recent cases operated upon, the clinical impressions of activity were confirmed at surgery.

Staphylococcus aureus and *Diplococcus pneumoniae* comprised 80% of the pathogens isolated in this series. These findings are similar to those listed by Eggston & Wolff (62). However, the organisms could often not be identified in the acute stage of disease when specific antibiotic therapy was instituted. Most cultures were obtained from spontaneous intranasal drainage during resolution or from

the lumen when the sinus was opened externally. This exudate was frequently sterilized by the previous antibiotic therapy.

Pathologic classifications of sinusitis suggested by Hajek (63), Eggston (64), and Schall (65) stressed the stage of disease, degeneration, and regeneration. Proetz (66) previously noted that these disease processes occurred simultaneously with areas of normal epithelium persisting in severe sinusitis. Specimens in this series revealed similar findings. No polyps were found in our specimens. Dixon (67) previously commented on similar experience. Perhaps the anatomic configuration of the frontal sinuses is not conducive to polyp formation.

Mucoceles and pyoceles were encountered in our series. Finck (68) believed the mucocele formed when the sinus ostium was blocked and goblet cells continued to secrete mucus. Turner (69) stressed that chronic inflammation was necessary for their formation and that their presence implied irreversible mucosal changes. It seems likely that partial obstruction of the nasofrontal duct predisposes to goblet cell proliferation in the frontal sinus because Hilding (70) noted a great increase in these cells in the occluded nostrils of dogs and rabbits. In our series, either trauma or surgery preceded the development of all mucoceles and pyoceles.

Bone may be as vulnerable as soft tissue to bacterial agents. Osteoporosis and osteitis were the most frequent pathologic findings. Osteoporosis may occur as a result of osteoclastic or halteresis processes causing the bone to become thinner and the trabeculae atrophic (71). In the osteitic or osteoblastic changes, the bone density increases. There is no exact correlation between bone and soft tissue disease, although osteoporosis with absorption of adjacent bone is more often associated with mucoceles and osteitis commonly accompanies chronic fibrotic sinusitis.

In frontal osteomyelitis the causative organism spreads along the venous channels in trabecular or lamellar bone and in marrow of diploic bone. Infection is usually first manifested at the junction of the anterior and posterior walls where the numerous channels in cancellous and diploic bone favor dissemination. Mosher (72) demonstrated the pathogenesis of osteomyelitis showing infected thrombi extending from the veins of the sinus mucosa to the diploe of the frontal bone. The gravity of this complication has been well documented by McNalley & Stuart (73) where subdural and brain abscess, cerebral venous thrombosis, and meningitis were the sequelae. The low incidence of osteomyelitis in this series was probably due to the intensive antibiotic therapy and relatively early surgical intervention in these patients.

Most tumors of the nose and sinuses are malignant. The squamous cell epithelioma is most common according to New & Erich (74). In the highly anaplastic variety there is disagreement in regard to pathologic classification. Godtfredson (75) maintains that many of these rightfully belong in the reticulum cell sarcoma group. Egerton & Wolff (76) on the other hand, believe that fibrosarcoma is the most common type of mesenchymal malignancy in the nose and accessory sinuses. There have also been differences of opinion regarding the cell types in our series.

Minor intranasal operative procedures such as irrigation, infraction of the middle turbinate, polypectomy, penetration of encroaching cells, and resection of the anterior middle turbinate are indicated as adjunct to medical therapy in acute and early chronic sinusitis. Pratt (77) described an intranasal approach to the frontal sinus through the bulla ethmoidalis by removal of sufficient bone, enlargement of the opening medially to the intrasinus septum, and removal of diseased mucosa with a ring curette. However it is unlikely that any medical or intranasal surgical procedure will cure a well-established chronic infection (59, 78).

Williams & Mousel (79) listed a number of

surgical principles to be followed in sinus surgery. Direct vision with adequate exposure and drainage along normal routes were considered important. Elimination of multiple cavities and the preservation of functioning nasal anatomy were also mentioned. They gave criteria for choosing between the external or internal approach to the sinuses. The external route was recommended for exteriorized disease, excessive pneumatization, a narrow ethmoid labyrinth, bony wall sclerosis, and secondary procedures. Generally the external approach has been advocated and favored because it is more direct, yielding better visualization, and there is less destruction to nasal physiology. These reasons appear valid to the author.

Trephination is a limited operation usually reserved for acute suppurative disease unresponsive to medical therapy. It is the primary procedure indicated in acute eroding sinusitis when drainage is necessary. The opening may be enlarged for a better view of the sinus interior.

In the extended trephination the opening in the sinus floor is enlarged to adequately inspect the mucosal lining and posterior sinus plate. Mucosa is removed when it appears irreversibly hyperplastic or polypoid, but a cuff of mucosa is spared at the nasofrontal duct orifice. Margins of eroded bone are removed from the anterior or posterior plates until normal appearing bone is noted. Granulations are removed from the dura when present. This procedure may be indicated in subacute or early chronic disease.

Prostheses, mostly polyethylene tubes, as stents for the nasofrontal duct were utilized in seven cases as recommended by Hugenberg & Williams (24) and Goodale (80). Our initial experience was encouraging but the tubes became plugged with dried secretions and several patients had an acute exacerbation of sinusitis with the patent tubes in place.

Reconstruction of the nasofrontal duct, as recommended by Sewall (18), Hoopie (81), Boyden (80) and Ogura et al. (21) failed in

three instances. Strictures formed and recurrent frontal sinusitis occurred.

There was reluctance to attempt the radical exenterations of Killian (11), Jansen (13) and Lynch (14). Anderson (82) earlier had noted the frequent failures due to incomplete surgery and closure of the frontonasal opening. McNalley & Stuart (73) stated that only three of fifteen operated patients remained symptom free. Also Goodale (83) in a review of 82 patients found a recurrence rate of over 50%. Thus combined external and internal frontal operations have fallen into disrepute because of the high incidence of residual disease and morbidity.

One indication for these extensive procedures is a malignancy of the nose and sinuses. An exploration is necessary to determine the extent of the disease, facilitate removal of the bulk of the tumor, and establish a nasal drainage route to eliminate the products of cellular disintegration produced by subsequent radiotherapy.

The obliteration originally described by Kuhnt (3) led to recurrent disease and was markedly deforming. However Goodale (84) in 1955 recommended a modification of the procedure: advising removal of the anterior and inferior walls, the sinus mucosa, a base leveling of the septa, and a complete ethmoidectomy. Disfigurement was corrected by autogenous bone grafting. In 1957 Goodale (85) reported favorable results with obliteration using a tissue implant of abdominal fat, and in 1965 he (33) emphasized the importance of removal of the mucous membrane from the nasofrontal duct and sinus cavity and the occlusion of the nasofrontal duct. He noted spontaneous obliteration by fibrous tissue and bone and believed that adipose tissue delayed or prevented osteogenesis. Skolnik et al (86) cautioned that the obliteration procedure was contraindicated in acute disease where drainage is necessary, and it has been our policy to perform the operation only in the chronic stage of disease.

Mucosa and bony septa are meticulously

removed from the sinus lumen. The anterior plate is removed and laterally to facilitate exposure. A cuff of mucosa of the nasofrontal duct is excised well into the nasal cavity and the opening is occluded with bone chips or soft tissue. On several occasions when the lateral nasofrontal duct and ethmoid cells were eroded, the communication between the nasal cavity and exenterated sinus was large. An enlarged opening into the nose also resulted when the ethmoidectomy was combined with the frontal exenteration without preservation of the lateral wall of the nasofrontal duct. Temporalis fascia, either folded or in sheet form, provided a satisfactory occlusion in these cases.

The osteoplastic anterior wall approach to the frontal sinus gives wide exposure and minimal deformity. Goodale & Montgomery (31, 32) in 1958 and 1964 reported successes with it. However Alford et al (87) in 1965 listed acute infections, fractures, osteomyelitis, and previous operations with extensive periosteal elevation as contraindications to the use of the osteoplastic flap. In many of these cases the frontal floor approach would appear applicable.

The osteoplastic flap was utilized on the first three obliteration operations, but the frontal floor approach was used on the subsequent procedures. It appears that this route is satisfactory for most oblitative procedures. In the poorly pneumatized sinus the frontal floor removal offers adequate exposure. For the highly pneumatized sinuses the anterior wall can be partially removed above and laterally without causing a notable external deformity. The use of a mirror, an angulated drill, and the operating microscope facilitate and ascertain removal of mucosa from the recesses.

Complications related to surgery for frontal sinusitis are not infrequent, but the incidence has been reduced in recent years by antibiotics and refinements in the operative procedures. In the early twentieth century disease was more likely to be eradicated by extensive procedures.

with removal of normal tissue adjacent to an inflammatory process (88 89 90)

Ocular complications are common because of the proximity to the operative site (40). Chronic upper lid edema is due to severance of lymphatics by an elongated curvilinear incision. Edema also occurs following faulty closure of the frontal incision when the scar is adherent to underlying bone. Hematoma is related to inadequate hemostasis in this highly vascular area. Wound infection results from tissue ischemia and contamination by *Staphylococcus aureus*, the nasal vestibule being the probable source of this pathogen.

The supraorbital nerve may be compressed by retraction or severed by the incision with resulting paresthesia or anesthesia. This complication is uncommon and can usually be avoided.

An incision made too low in the upper lip may sever the levator muscle with resulting ptosis. Careful palpation of the bony landmarks of the frontal floor will prevent this complication.

Extraocular muscles may be injured. The trochlea and tendon of the superior oblique or the superior medial orbital wall are most vulnerable. Killian (11) avoided damage to the trochlea by removal of the frontal sinus floor from above and stated that fibrous strands connected to the supraorbital ridge helped maintain its normal position. Kuhst (3) had noted earlier that displacement of the trochlea caused diplopia which subsided in a short period of time. Our experience has been similar. Subperiosteal dissection without laceration and accurate reapproximation should prevent any palsy.

The inferior oblique muscle can also be injured on the inferior medial orbital wall during a fronto-ethmoid extirpation. This muscle origin is usually just lateral to the bony opening of the nasolacrimal canal, and in this location it should not be injured by an ethmoidectomy. However Whitnall (91) in a study of 100 orbits, found that the origin was 2 to 7 mm higher in 55. Here it lies in the proximity of the ethmoid dissection. Thus, anomalous

origin appears to be the best explanation for this complication. If the orbital periosteum is inadvertently opened during curettage of the fronto-ethmoid cells, the medial and superior rectus muscles may be directly lacerated. The more remote possibility of perforation of the eyeball should also be mentioned.

The lacrimal sac may be damaged by an inferiorly placed incision or by curettage of the ethmoid cells adjacent to the posterior lacrimal crest. However the fundus of the sac should be identified as a bluish dome-shaped structure 4-5 mm in diameter lying in the lacrimal fossa.

Avulsion or severance of the medial canthal ligament results in the lateral displacement of the inner canthus. If severed, it can be reapproximated by a nonabsorbable suture. If avulsed with no bony attachment remaining, burr holes are made in the lateral nasal wall to anchor the ligament to its former site.

The optic nerve may be injured in a posterior ethmoidectomy where the distance separating ethmoid cells from the optic foramen is only 5 mm. Trauma is effected by too vigorous retraction on the overlying periosteum or by laceration of it during curettage of the cells. Obviously extreme caution should be exercised in this area.

Cerebrospinal fluid leaks are produced by trauma perforating the anterior fossa dura beneath the posterior sinus wall or the cribriform plate beneath the posterior nasofrontal duct. Meningitis, brain abscess, or cerebral venous thrombosis are possible complications from such an exposure in an infected sinus, and antibiotic prophylaxis is indicated.

Calvert (92) believed that intracranial infection could come from sinuses that were not infected, and Work (60) recommended ablation after compound fractures because of these serious complications. McHugh (93) found dural lacerations beneath the displaced bone fragments away from the site of the fracture lines. Dural tears can be sutured with small lacrimal needles, and dural defects may be covered with a fascial graft.

Osteomyelitis has been reported following frontal sinus surgery (94) Schenk (95) emphasized that antibiotics and chemotherapy have reduced the incidence and severity of the disease. This rare complication is more likely if diploic bone is exposed to suppuration. The possibility of overlooking early bone involvement at the primary operation must be considered. Williams (79) stated that osteomyelitis begins in the cancellous bone of the nasion and spreads to the frontal bone by thrombophlebitis of the vein of Breschet a large fairly constant vessel passing in this region. He believed the Killian procedure which interrupted this communication prevented the disease from reaching the frontal bone.

It appears that current surgical refinements, with separation of the frontal and ethmoid procedures when indicated and the utilization of obliteration have considerably reduced the operative complication rate. A recent series of 100 cases reported by Zonis, Montgomery & Goodale (94) included only five secondarily infected hematomas, one thrombophlebitis and nonfatal pulmonary embolism and one lacerated anterior fossa dura with cerebrospinal fluid leak. As a comparison McNalley & Stuart (73) in a 30 year review reported in 1954

listed an overall complication rate of 60% in acute and 40% in chronic frontal sinusitis.

All previous operations from the simple trephine to the radical Jansen, Ritter & Lynch procedures were followed by a high incidence of recurrent disease. The enlarged debrided nasofrontal duct became a strictured nonfunctioning communication. More physiologic nasofrontal duct reconstructions with mucosa and skin grafts reduced the recurrence rate considerably but failures were frequent in larger series. Strictures prevented adequate drainage from above and predisposed to ascending infection from below.

With acknowledgement of failure to maintain a functional nasofrontal duct and promote regeneration of normal sinus mucosa, removal of all sinus mucosa and permanent occlusion of the nasal opening seems to be the only alternative procedure. The obliteration, eliminating the exenterated sinus as a functioning organ, has produced better results than any previous operation. In the large series reported by Zonis, Montgomery & Goodale (94) there was only a 3% failure rate. This smaller series reported compares favorably with no recurrences being observed at this time.

Summary and Conclusions

The history of frontal sinus surgery is reviewed and trends in conservative and radical surgical procedures are documented. Revival of previously advocated operations with current modifications is noted.

Surgical anatomy of the frontonasal area is reviewed and certain variations and landmarks are stressed.

Physiologic principles related to frontal sinus surgery are discussed.

Thirty-one patients with frontal sinusitis operated upon over a period of 20 years are reviewed. The following pertinent observations are noted:

- 1 Etiologic factors of significance are as isolated maxillary and ethmoid sinusitis and frontal sinus trauma.

- 2 Radiologic interpretation of activity of disease is difficult with conventional views, but polytomography often reveals specific changes.

- 3 *Staphylococcus aureus* and *Diplococcus pneumoniae* are the most frequent pathogens cultured.

- 4 Pathologic findings often demonstrated are irreversible mucosal disease and bone absorption.

- 5 Surgical procedures of incision, drainage and trephine lead to a high recurrence rate.

6 The obliteration procedure, utilizing the osteoplastic flap or frontal floor approach, reduces the recurrence rate and seems to be the

procedure of choice for chronic recurrent frontal sinusitis.

34. Sanders, S. H. 1963. Is a permanent maxillofrontal opening in surgery for chronic suppurative disease of the fronto-ethmo-sphenoid complex of sinuses

Osteomyelitis has been reported following frontal sinus surgery (94) Schenk (95) emphasized that antibiotics and chemotherapy have reduced the incidence and severity of the disease. This rare complication is more likely if diploic bone is exposed to suppuration. The possibility of overlooking early bone involvement at the primary operation must be considered. Williams (79) stated that osteomyelitis begins in the cancellous bone of the nasion and spreads to the frontal bone by thrombophlebitis of the vein of Breschet, a large fairly constant vessel passing in this region. He believed the Killian procedure which interrupted this communication prevented the disease from reaching the frontal bone.

It appears that current surgical refinements, with separation of the frontal and ethmoid procedures when indicated and the utilization of obliteration have considerably reduced the operative complication rate. A recent series of 100 cases reported by Zonis, Montgomery & Goodale (94) included only five secondarily infected hematomas, one thrombophlebitis and nonfatal pulmonary embolism, and one lacerated anterior fossa dura with cerebrospinal fluid leak. As a comparison McNalley & Stuart (73) in a 30 year review reported in 1954

listed an overall complication rate of 60% in acute and 40% in chronic frontal sinusitis.

All previous operations from the simple trephine to the radical Jansen, Ritter & Lynch procedures were followed by a high incidence of recurrent disease. The enlarged debrided nasofrontal duct became a strictured nonfunctioning communication. More physiologic nasofrontal duct reconstructions with mucosa and skin grafts reduced the recurrence rate considerably but failures were frequent in larger series. Strictures prevented adequate drainage from above and predisposed to ascending infection from below.

With acknowledgement of failure to maintain a functional nasofrontal duct and promote regeneration of normal sinus mucosa, removal of all sinus mucosa and permanent occlusion of the nasal opening seems to be the only alternative procedure. The obliteration, eliminating the exenterated sinus as a functioning organ, has produced better results than any previous operation. In the large series reported by Zonis, Montgomery & Goodale (94) there was only a 3% failure rate. This smaller series reported compares favorably with no recurrences being observed at this time.

Summary and Conclusions

The history of frontal sinus surgery is reviewed and trends in conservative and radical surgical procedures are documented. Revival of previously advocated operations with current modifications is noted.

Surgical anatomy of the frontonasal area is reviewed and certain variations and landmarks are stressed.

Physiologic principles related to frontal sinus surgery are discussed.

Thirty-one patients with frontal sinusitis operated upon over a period of 20 years are reviewed. The following pertinent observations are noted:

1. Etiologic factors of significance are associated maxillary and ethmoid sinusitis and frontal sinus trauma.

2. Radiologic interpretation of activity of disease is difficult with conventional views, but polytomography often reveals specific changes.

3. *Staphylococcus aureus* and *Diplococcus pneumoniae* are the most frequent pathogens cultured.

4. Pathologic findings often demonstrated are irreversible mucosal disease and bone absorption.

5. Surgical procedures of incision, drainage and trephine lead to a high recurrence rate.

Preface

One cannot usually foretell from what aspect a biological enigma should be attacked to lead in the most direct fashion to a solution. Ootosclerosis is at present a biological enigma. Facts about otosclerosis may be gathered by several means and may be considered in several ways and in the light of different disciplines. The future alone will tell us whether any of the facts and reasoning currently available are the keys to the problem. At present we cannot foretell (H. M. Frost, M.D. 1962).

The variety and volume of experimental data on otosclerosis which have accumulated during the past decade as well as their increasingly rapid appearance make attempts at evaluating the *status quo* of research in this field exceedingly difficult. It is our opinion that a comprehensive review of the subject with emphasis on recent biochemical contributions would be a valuable addition to the literature. An attempt at such a review is presented below.

Histopathology

Otosclerosis is a disease of the bony labyrinthine capsule, often developing in areas in which embryonic cartilage persists. Viewed under the light microscope, the pathological process is characterized by resorption of normal bone often around blood vessels and its replacement with cellular fibrous connective tissue. Areas undergoing active resorption contain numerous osteoclasts and are extensively vascularized. Within the matrix of the invading connective tissue reticular cells and fibroblasts assume the character and activity of osteoblasts and later osteocytes. Calcium is deposited irregularly in the matrix, resulting in the formation of an immature weblike bone. This bone contains a large amount of ground substance with few collagen fibers, hence its blue color (basophilia) when stained with hematoxylin and eosin. The immature bone is eventually resorbed and replaced by a different type of weblike bone containing little ground substance and large numbers of collagen fibers. This is sclerophilic and stains red with hematoxylin and eosin. Finally true lamellar bone may be laid down within the weblike bone with the result that the

otosclerotic focus assumes a mosaic like appearance. The process of resorption and replacement continues irregularly both within the focal area and at its margin. Microfoci, demonstrable only with the electron microscope, occur in the vicinity of the larger more evident foci and the lesion appears to enlarge by fusion of these microfoci (Chevance et al., 1969). Under the light microscope extension of the disease manifests itself as a network of trabeculae.

Otosclerotic foci may remain active or become quiescent. Active lesions are characterized microscopically by the spongy appearance of the bone, by the presence of large numbers of cells, especially osteoclasts, and by extensive vascularization. Inactive otosclerotic lesions exhibit a more compact bone, are poorly vascularized, and contain few cells. Foci within the same temporal bone may be in the same or different stages of activity. A single lesion may contain both active and quiescent regions. Finally as the disease progresses, a focus may exhibit alternating periods of activity and quiescence as it proceeds to its inactive terminal stage.

Occurrence of Otosclerotic Foci Areas of Predilection

An otosclerotic lesion may occur in any region of the bony labyrinthine capsule. Only rarely is it located external to this area in which case it may appear in the carotid canal segment, cochleariform process, or incudo-stapedial or incudo-malleolar joints (Nager 1969). Most frequently (80 to 90 percent of all cases) the primary lesion is found in the region anterior to the oval window (Guild, 1944; Nylen, 1949; Flescher 1958; Belekert, 1963). Despite the

high incidence of foci in this area, in only approximately 10 percent of these cases does the disease invade the annular ligament and spread to the stapedial footplate causing ankylosis. The latter manifests itself clinically as the conductive deafness characteristic of otosclerosis. Isolated primary otosclerosis of the footplate is rare, observed in only 12 percent of the cases studied by Guild (1944) and in 5 percent of the cases studied by Rüedi &

Fig 2 A external auditory canal; B malleus and tympanic membrane; C incus; D stapes; E otosclerotic foci; F vestibule; G facial nerve; H semicircular

canals; I cochlea; J tympanic cavity; K, eustachian tube; L, internal auditory canal.

causes ankylosis of the stapes resulting in a conductive deafness. Since the latter complicates only approximately 10 percent of all cases of otosclerosis, histological examination of the otic capsule is necessary in order to ascertain the true incidence of the disease, hence the term "histological otosclerosis". Therefore, studies giving statistics of the incidence of clinical otosclerosis are descriptive only of the incidence of stapedial ankylosis. Studies giving data describing the distribution of "histological" otosclerosis, however, are surveys of the total incidence of the disease regardless of whether or not it is clinically manifest.

Information concerning the ratio of distribution of otosclerosis between the sexes derives from both clinical and histological investigations. Numerous authors have reported the incidence of stapedial ankylosis in females to be twice that in males (Baier & Stern, 1925

Davenport et al 1933 Schmidt, 1933 Gray 1934 Nager 1939 Cawthorne, 1955 Shambaugh, 1956 Wolff, 1958 Larsson, 1960 Hlavacek & Chladek, 1963 Altmann et al., 1967). Our own analysis of 2 600 operative cases of otosclerosis yields a sex ratio of 1.6 females to 1.0 males (Soder et al., unpublished data). However histological studies have shown the incidence of otosclerosis to be approximately equal in males and females (Weber 1935 Engström, 1940 Guild, 1944 Altmann et al., 1967). Analysis of data combined from a number of the larger studies shows the incidence of histological otosclerosis to be 51.5 percent in males and 48.5 percent in females, giving a ratio of 1.00 males to 0.94 females. The incidence of stapedial ankylosis is reported to be 38.2 percent in males and 61.8 percent in females, a ratio of 1.61 females to 1.00 males (Altmann et al., 1967).

Fig 1 A tympanic cavity B otosclerosis in foot plate C vestibule D otosclerotic foci E cochlea.

Spöndlin (1957) Another region frequently affected (often simultaneously with that of the oval window) is the area of the round window. The latter is involved in 30 to 40 percent of all cases (Guild 1944 Nylén 1949 Fleischer 1958 Rüedi & Spöndlin 1957). Less often otosclerotic foci occur in other areas of the capsule, e.g. in the cochlear and semi-circular canal regions and/or at the anterior circumference of the internal auditory meatus.

Although otosclerosis is usually focal (90 percent of all cases) it can develop as a diffuse process involving large areas of the otic capsule. The diffuse variety normally results from confluence of the focal areas, but primary diffuse otosclerosis does occur.

In most cases otosclerosis affects both temporal bones, unilateral otosclerosis occurring in only 25 percent of all cases (Guild 1944 Nylén, 1949 Fleischer 1958).

Incidence of Otosclerosis

Sex Ratio and Demographic Distribution

In any assessment of the ratio of distribution of otosclerosis between the sexes or of the incidence of the disease in various populations,

one must appreciate the distinction between clinical and "histological" otosclerosis. The disease can be detected clinically only if it

Fig. 2 A external auditory canal, B malleus and tympanic membrane, C incus, D stapes, E otosclerotic foci, F vestibule, G facial nerve, H semicircular

canals, I cochlea, J tympanic cavity, K eustachian tube, L internal auditory canal.

causes ankylosis of the stapes resulting in a conductive deafness. Since the latter complicates only approximately 10 percent of all cases of otosclerosis, histological examination of the otic capsule is necessary in order to ascertain the true incidence of the disease, hence the term "histological otosclerosis". Therefore, studies giving statistics of the incidence of clinical otosclerosis are descriptive only of the incidence of stapedial ankylosis. Studies giving data describing the distribution of histological otosclerosis, however, are surveys of the total incidence of the disease, regardless of whether or not it is clinically manifest.

Information concerning the ratio of distribution of otosclerosis between the sexes derives from both clinical and histological investigations. Numerous authors have reported the incidence of stapedial ankylosis in females to be twice that in males (Bauer & Stein, 1925

Davenport et al., 1933 Schmidt, 1933 Gray 1934 Nager 1939 Cawthorne, 1955 Shambaugh, 1956 Wolff 1958 Larsson, 1960 Hlavacek & Chladek, 1963 Altmann et al., 1967). Our own analysis of 2 600 operative cases of otosclerosis yields a sex ratio of 1.6 females to 1.0 males (Solfer et al., unpublished data). However histological studies have shown the incidence of otosclerosis to be approximately equal in males and females (Weber 1935 Engström, 1940 Guild, 1944 Altmann et al., 1967). Analysis of data combined from a number of the larger studies shows the incidence of histological otosclerosis to be 51.5 percent in males and 48.5 percent in females, giving a ratio of 1.00 males to 0.94 females. The incidence of stapedial ankylosis is reported to be 38.2 percent in males and 61.8 percent in females, a ratio of 1.61 females to 1.00 males (Altmann et al. 1967).

Both clinical and histological studies of incidence have limitations, to a greater or lesser degree, which must be appreciated when evaluating their validity. Although figures pertaining to clinical otosclerosis are computed from a large number of cases and thus are statistically significant, the cases included are not entirely unselected to the extent that patients are by definition unrepresentative of the entire population. In fact, the higher incidence of clinical otosclerosis in females may be a reflection of a "natural selectivity" among the patients themselves i.e. it may be due to a greater willingness of females to consult a physician about hearing impairment.

The results of the histological studies of the incidence of the disease are even more difficult to evaluate than are those of the clinical studies. In addition to suffering from selectivity the data are not statistically significant because of the small number of temporal bones available for examination. In fact, the number of temporal bones which would be required in order to obtain significant data is impracticably large. The largest series analysed to date (Guild 1944) includes 974 temporal bones of which only 47 were found to exhibit otosclerosis.

It is clear that a method other than histological examination of temporal bones is essential in order to obtain significant data of the total incidence of the disease. The comparatively recent technique of polytome laminography (Derlacki & Valvassori 1965). The advantages of this technique are that otosclerotic lesions can be detected in the living patient and that the locations and extent of the lesions throughout the otic capsule can be visualized. The problem of non-random selection of persons would remain but it is likely that with the extremely large numbers of persons who can easily be examined by this method, collection of valid data is at least feasible.

The available data on the frequency of occurrence of otosclerosis in various populations suffer from the same limitations as those pertaining to the sex ratio. They are not statistically significant, either because the cases studied were not entirely unselected or because they were too few in number. However some assessment of the distribution of the disease can be derived from them if the restrictions on their validity are kept in mind. A compilation of figures from the studies of Engström (1940) and Guild (1944) indicates that among 601 white American adults, the incidence of otosclerosis is 8.3 percent while the incidence of stapedial ankylosis is only 0.99 percent (Altmann et al 1967). That is, although every tenth white adult has otosclerosis, hearing difficulties affect only every one hundredth individual. Information on the incidence of the disease in populations other than those of white American adults is limited. A study of temporal bones of adult American Negroes indicated that otosclerosis is seven times less frequent than in the adult white population (Altmann et al 1967). The few existing investigations of otosclerosis in African Negroes (Van Fick, 1964) and in American Indians (Gregg et al 1963) suggested that the disease is almost nonexistent in the populations studied. Otosclerosis also appears to be extremely rare in Japanese (Horiguchi 1953, Takahara et al., 1959), Chinese (Altmann et al., 1967) and Indonesian (Nizar 1960) populations. However the incidence of stapedial ankylosis in populations of both Northern and Southern India is high, 20 to 30 percent as compared with 10 percent in white American populations (Sinha 1963, Kapur & Patti, 1966). These limited data suggest that otosclerosis is of relatively frequent occurrence only in white American and in Indian populations.

Etiology of Otosclerosis The Genetic Basis

The familial pattern of otosclerotic deafness observed stimulated investigations which proved the disease to be heritable. A clinical study of 257 families with otosclerosis demonstrated the mode of inheritance to be a simple autosomal dominance with a penetrance of the abnormal gene of 25 ± 8.5 percent (Larsson, 1960). A survey by Morrison (1967) of 146 otosclerotic patients and their families corroborated the pattern of inheritance but established penetrance at 40 percent.

It is interesting that "isolated" instances of otosclerosis in the offspring of matings between apparently normal parents accounted for 43 cases, or 30 percent of all cases included in Morrison's study. With a penetrance of only 40 percent, most of these cases can be explained by assuming that the abnormal gene is present in the parents' genotype but fails to manifest itself phenotypically. New autosomal dominant mutations can account for only a small percentage of the isolated cases. Morrison calculates that 1.4 percent of the abnormal alleles are dropped per generation and that the theoretical mutation rate is of the order of $49 \cdot 10^{-10}$. Thus, only two out of 43 (4.7 percent) of these cases are theoretically likely to be due to new mutations. Since, however, the isolated cases are statistically more frequent among secondary births, it is probable that at least some are due to new mutant alleles. A few cases might result from an alternate mode of inheritance e.g., homozygous autosomal recessivity. Indeed, the phenomenon of similar phenotypes resulting from different genotypes does occur in man. Finally, some cases may be caused not by otosclerosis but rather by other diseases producing a conductive deafness mimicking that of otosclerosis. This possibility cannot be ruled out in a purely clinical study.

Since otosclerosis is not a sex-linked charac-

ter one would expect a sex ratio incidence of 1:1. As mentioned above, histological studies of temporal bones have confirmed that this ratio prevails. Observations from purely clinical studies indicate that otosclerosis occurs twice as frequently in females as in males, possibly for the behavioral reason mentioned previously. However, Morrison's random sampling of 613 individuals, from which he obtained the 146 otosclerotics included in his study yielded the following results. Of 338 females, 137 (40.5 percent) had otosclerosis of 275 males, 88 (32 percent) were otosclerotic. In this case, the sex ratio from a clinical study is near unity.

The possibility of a linkage between otosclerosis and characters for which the genetics are well-established has been investigated, as has the occurrence of abnormal karyotypes. Januszewska (1929) investigated five families with otosclerosis and observed a linkage between otosclerosis and the ABO blood group system. However, the validity of the results in Januszewska's study is questionable because of incomplete genotyping and the probability that the observed deafness was actually caused by otosclerosis in only two of the five families. In a study of over one hundred otosclerotics, Morrison (1967) found no evidence of any association of otosclerosis with a particular genotype in the ABO, MN, or Rhesus blood groups, the secretor status, or with a specific or abnormal haptoglobin genotype. With respect to the latter we have also reported a normal distribution of serum haptoglobin among otosclerotics (Soffer et al., 1963). An association of otosclerosis with the ability to taste phenylthiocarbamide is statistically significant (Morrison, 1967) indicating that alleles for the two characters are located quite close to each other on the same chromosome. Tato and co-workers (1963) reported the presence of chromosome ab-

Both clinical and histological studies of incidence have limitations, to a greater or lesser degree, which must be appreciated when evaluating their validity. Although figures pertaining to clinical otosclerosis are computed from a large number of cases and thus are statistically significant, the cases included are not entirely unselected to the extent that patients are by definition unrepresentative of the entire population. In fact, the higher incidence of clinical otosclerosis in females may be a reflection of a "natural selectivity" among the patients themselves i.e. it may be due to a greater willingness of females to consult a physician about hearing impairment.

The results of the histological studies of the incidence of the disease are even more difficult to evaluate than are those of the clinical studies. In addition to suffering from selectivity the data are not statistically significant because of the small number of temporal bones available for examination. In fact, the number of temporal bones which would be required in order to obtain significant data is impractically large. The largest series analysed to date (Guild, 1944) includes 974 temporal bones of which only 47 were found to exhibit otosclerosis.

It is clear that a method other than histological examination of temporal bones is essential in order to obtain significant data of the total incidence of the disease. The comparatively recent technique of polytome laminography would seem to be the most promising alternative (Deriacki & Valvassori 1965). The advantages of this technique are that otosclerotic lesions can be detected in the living patient and that the locations and extent of the lesions throughout the otic capsule can be visualized. The problem of non-random selection of persons would remain but it is likely that with the extremely large numbers of persons who can easily be examined by this method, collection of valid data is at least feasible.

The available data on the frequency of occurrence of otosclerosis in various populations suffer from the same limitations as those pertaining to the sex ratio. They are not statistically significant, either because the cases studied were not entirely unselected or because they were too few in number. However some assessment of the distribution of the disease can be derived from them if the restrictions on their validity are kept in mind. A compilation of figures from the studies of Engström (1940) and Guild (1944) indicates that among 601 white American adults, the incidence of otosclerosis is 8.3 percent while the incidence of stapedial ankylosis is only 0.99 percent (Altmann et al. 1967). That is, although every tenth white adult has otosclerosis, hearing difficulties affect only every one hundredth individual. Information on the incidence of the disease in populations other than those of white American adults is limited. A study of temporal bones of adult American Negroes indicated that otosclerosis is seven times less frequent than in the adult white population (Altmann et al. 1967). The few existing investigations of otosclerosis in African Negroes (Van Fick 1964) and in American Indians (Gregg et al. 1965) suggested that the disease is "almost non-existent" in the populations studied. Otosclerosis also appears to be extremely rare in Japanese (Horiguchi, 1953; Takahara et al. 1959), Chinese (Altmann et al. 1967), and Indonesian (Nizar 1960) populations. However the incidence of stapedial ankylosis in populations of both Northern and Southern India is high: 20 to 30 percent as compared with 10 percent in white American populations (Sinha 1963; Kapur & Patt, 1966). These limited data suggest that otosclerosis is of relatively frequent occurrence only in white American and in Indian populations.

Etiology of Otosclerosis The Genetic Basis

The familial pattern of otosclerotic deafness observed stimulated investigations which proved the disease to be heritable. A clinical study of 257 families with otosclerosis demonstrated the mode of inheritance to be a simple autosomal dominance with a penetrance of the abnormal gene of 25 ± 8.5 percent (Larson, 1960). A survey by Morrison (1967) of 146 otosclerotic patients and their families corroborated the pattern of inheritance but established penetrance at 40 percent.

It is interesting that "isolated" instances of otosclerosis in the offspring of matings between apparently normal parents accounted for 43 cases, or 30 percent of all cases included in Morrison's study. With a penetrance of only 40 percent, most of these cases can be explained by assuming that the abnormal gene is present in the parents' genotype but fails to manifest itself phenotypically. New autosomal dominant mutations can account for only a small percentage of the isolated cases. Morrison calculates that 1.4 percent of the abnormal alleles are dropped per generation and that the theoretical mutation rate is of the order of $49 \cdot 10^{-6}$. Thus, only two out of 43 (4.7 percent) of these cases are theoretically likely to be due to new mutations. Since however the isolated cases are statistically more frequent among secondary births, it is probable that at least some are due to new mutant alleles. A few cases might result from an alternate mode of inheritance—e.g. homozygous autosomal recessivity. Indeed, the phenomenon of similar phenotypes resulting from different genotypes does occur in man. Finally, some cases may be caused not by otosclerosis but rather by other diseases producing a conductive deafness mimicking that of otosclerosis. This possibility cannot be ruled out in a purely clinical study.

Since otosclerosis is not a sex-linked charac-

ter one would expect a sex ratio incidence of 1:1. As mentioned above, histological studies of temporal bones have confirmed that this ratio prevails. Observations from purely clinical studies indicate that otosclerosis occurs twice as frequently in females as in males, possibly for the behavioral reason mentioned previously. However Morrison's random sampling of 613 individuals, from which he obtained the 146 otosclerotics included in his study yielded the following results. Of 338 females, 137 (40.5 percent) had otosclerosis of 275 males, 88 (32 percent) were otosclerotic. In this case, the sex ratio from a clinical study is near unity.

The possibility of a linkage between otosclerosis and characters for which the genetics are well-established has been investigated, as has the occurrence of abnormal karyotypes. Jannezzia (1929) investigated five families with otosclerosis and observed a linkage between otosclerosis and the ABO blood group system. However the validity of the results in Jannezzia's study is questionable because of incomplete genotyping and the probability that the observed deafness was actually caused by otosclerosis in only two of the five families. In a study of over one hundred otosclerotics, Morrison (1967) found no evidence of any association of otosclerosis with a particular genotype in the ABO, MN or Rhesus blood groups, the secretor status, or with a specific or abnormal hapto-globin genotype. With respect to the latter we have also reported a normal distribution of serum haptoglobin among otosclerotics (Soffer et al., 1963). An association of otosclerosis with the ability to taste phenylthiocarbamide is statistically significant (Morrison, 1967) indicating that alleles for the two characters are located quite close to each other on the same chromosome. Taito and co-workers (1963) reported the presence of chromosome ab-

normalities in otosclerosis, i.e. trisomy and tetrasomy in patients aged 13 to 15 years. However in chromosome studies of nine cases of otosclerosis and three cases of osteogenesis imperfecta, Morrison (1967) found no abnormal karyotypes. More extensive studies are necessary to resolve this conflict.

The association of (conductive) deafness with osteogenesis imperfecta and blue sclerae has been documented by authors since the syndrome was originally described by van der Hoeve and de Kleyn. Wullstein and co-workers (1960) and Ogilvie & Hall (1962) argued from results of histological studies that otosclerosis is a local manifestation of osteogenesis imperfecta, indicating that both are determined by the same abnormal allele. It is true that a large number of children affected with osteogenesis (with or without blue sclerae) who survive to adult life develop deafness which follows a clinical pattern similar to that of otosclerosis. In Smår's (1961) study of individuals with osteogenesis imperfecta, 22.6 percent have some degree of deafness, the age-of-onset pattern mimicking that of otosclerosis. As in the otosclerosis, the severity of the deafness in osteogenesis was enhanced by pregnancy and varied among families, the most serious cases beginning in adolescence and progressing rapidly.

Despite such similarities, the numerous genetic, histological and biochemical factors which differ between otosclerosis and osteogenesis imperfecta suggest that the theory of a common abnormal gene is untenable. Otosclerosis occurs only in man, whereas osteogenesis has been demonstrated in other animals (Ogilvie & Hall 1962). Isolated cases are frequent in otosclerosis (30 percent) rarer in osteogenesis (approximately 9 percent). Blue sclerae are associated with otosclerosis in less than 0.5 percent of all cases, while 85 percent of all individuals with osteogenesis have blue sclerae.

Deafness in otosclerosis is severe and sensorineural in less than 10 percent of all cases in osteogenesis: severe sensorineural hearing loss is much more frequent, occurring in 40 percent of all cases. Secondary manifestations of osteogenesis imperfecta are widespread (bones, joints, sclerae, teeth, blood vessels) no skeletal abnormalities or hemorrhages were found associated with otosclerosis. In Morrison's study where otosclerosis and osteogenesis imperfecta co-exist, the two may be clearly distinguished histologically (Altmann & Kornfeld, 1967; Bretlau & Balslev-Jørgensen, 1969) osteoclasts are absent and fibroblasts infrequent in osteogenesis while both are common in otosclerosis (Chevance, 1965; Clerc & Chevance, 1965). Free sulphhydryl groups were detected biochemically in otosclerotic foci but not in osteogenic bone (Chevance, 1965). Finally otosclerosis is a common disease, osteogenesis is rare.

It may be concluded that there is no good evidence in support of the hypothesis that the two conditions result from the same abnormal gene. The evidence is good, however that they belong to the same family of diseases, the inherited collagen abnormalities. All of the latter have an autosomal dominant mode of inheritance with incomplete penetrance of the abnormal gene. Phenotypically the expression varies that is, there are degrees of clinical severity. In all of these diseases the defect probably affects the same enzyme system, that concerned with the production and turnover of collagen. Deafness in osteogenesis is described by Morrison (1967) as a "phenocopy" of otosclerosis. Additional "phenocopies" of otosclerosis may include Paget's disease (osteitis deformans), congenital absence of the stapes, rheumatoid arthritis (with involvement of ossicular joints), Von Recklinghausen's disease (osteitis fibrosa cystica), and chronic adhesive otitis.

Basic Research on Pathogenesis The Biochemical Data

Until recently the major contribution to expansion of knowledge of the pathogenesis of otosclerosis derived from histological and histochemical data. Histological studies have been invaluable in defining the morphological changes characterizing the disease process and in describing the microscopic appearance of the lesion. Histochemical studies have shown that otosclerotic foci are metabolically active, particularly during the stages of growth and invasion. However the procedures employed in histochemistry have inherent technical difficulties which restrict the amount and type of information which can be extracted from them. Identification and quantitative measurement of small molecular imbalances and highly specific chemical reactions require the more sensitive techniques of biochemical analysis. Ultimately histological and histochemical descriptions of morphological events must be correlated with biochemical information in order to construct a complete and accurate picture of the otosclerotic process.

Biochemical data on otosclerosis are not abundant. However since Maurer's initial study in 1961 information has been forthcoming at an increasing rate. To date, biochemical studies of otosclerosis have focused on four major tissue constituents: enzymes, components of the bone matrix, hormones, and inorganic constituents of bone.

ENZYMES

Since otosclerosis is a genetically-determined disease, it is likely that the initial biochemical manifestation is either a defective control of the synthesis of an enzyme(s) or the production of a completely or partially non-functional enzyme(s). The biochemical search for aberrant enzyme behaviour was given an impetus by

significant histochemical findings. Albermar & Covell (1961) found large amounts of succinate dehydrogenase and cytochrome oxidase in osteoclasts, fibroblasts, blood vessel walls (and smaller amounts in osteocytes) of otosclerotic foci when compared with control stapedes, suggesting that the former have a high level of respiratory activity. Large concentrations of acid phosphatase have been demonstrated in osteoclasts and in the matrix of otosclerotic bone (Albermar & Covell, 1961). Alkaline phosphatase has been detected both in the cells (osteoblasts, osteoclasts, fibroblasts) and in the otosclerotic matrix (Ricci, 1962; Arslan & Ricci, 1963). Leucine aminopeptidase (Alberti & Tarikainen, 1963) and the non-specific esterase complex (Ardouni & Wegmann, 1961; Chevance, Clerc & Bouche, 1962; Alberti & Tarikainen, 1963) have been found in blood vessel walls, perivascular fibroblasts, and particularly in osteocytes close to blood vessels in the otosclerotic focus. Cabrini (1961) however found leucine aminopeptidase activity in the focus to be completely extracellular.

Despite their desirability comparative biochemical studies of enzyme activity in otosclerotic and normal bone are relatively few. Maurer's pioneer study (1961/62) indicated that there is an increase in the total nitrogen content and a decrease in alkaline phosphatase activity in endochondral bone (osicles, semicircular canal, promontory) from otosclerotics. Maurer concluded that these results were inexplicable on the assumption of an increase in the number or activity of cellular elements (metabolically active) but rather derived from a numerical increase in the fibrils (metabolically inactive). We have carried out comparative studies of extractable protein and certain enzymes (lactate dehydrogenase, malate dehydrogenase, amino aspartic transferase, al-

normalities in otosclerosis i.e. trisomy and tetrasomy in patients aged 13 to 15 years. However in chromosome studies of nine cases of otosclerosis and three cases of osteogenesis imperfecta, Morrison (1967) found no abnormal karyotypes. More extensive studies are necessary to resolve this conflict.

The association of (conductive) deafness with osteogenesis imperfecta and blue sclerae has been documented by authors since the syndrome was originally described by van der Hoeve and de Kleyn. Wullstein and co-workers (1960) and Ogilvie & Hall (1962) argued from results of histological studies that otosclerosis is a local manifestation of osteogenesis imperfecta, indicating that both are determined by the same abnormal allele. It is true that a large number of children affected with osteogenesis (with or without blue sclerae) who survive to adult life develop deafness which follows a clinical pattern similar to that of otosclerosis. In Smårs (1961) study of individuals with osteogenesis imperfecta, 22.6 percent have some degree of deafness, the age-of-onset pattern mimicking that of otosclerosis. As in the otosclerosis, the severity of the deafness in osteogenesis was enhanced by pregnancy and varied among families, the most serious cases beginning in adolescence and progressing rapidly.

Despite such similarities the numerous genetic, histological and biochemical factors which differ between otosclerosis and osteogenesis imperfecta suggest that the theory of a common abnormal gene is untenable. Otosclerosis occurs only in man, whereas osteogenesis has been demonstrated in other animals (Ogilvie & Hall, 1962). "Isolated" cases are frequent in otosclerosis (30 percent) rarer in osteogenesis (approximately 9 percent). Blue sclerae are associated with otosclerosis in less than 0.5 percent of all cases, while 85 percent of all individuals with osteogenesis have blue sclerae.

Deafness in otosclerosis is severe and sensorineural in less than 10 percent of all cases. In osteogenesis, severe sensorineural hearing loss is much more frequent, occurring in 40 percent of all cases. Basic Research on Pathogenesis The Biochemical Data

Until recently the major contribution to expansion of knowledge of the pathogenesis of otosclerosis derived from histological and histochemical data. Histological studies have been invaluable in defining the morphological changes characterizing the disease process and in describing the microscopic appearance of the lesion. Histochemical studies have shown that otosclerotic foci are metabolically active, particularly during the stages of growth and invasion. However the procedures employed in histochemistry have inherent technical difficulties which restrict the amount and type of information which can be extracted from them. Identification and quantitative measurement of small molecular imbalances and highly specific chemical reactions require the more sensitive techniques of biochemical analysis. Ultimately histological and histochemical descriptions of morphological events must be correlated with biochemical information in order to construct a complete and accurate picture of the otosclerotic process.

Biochemical data on otosclerosis are not abundant. However since Maurer's initial study in 1961 information has been forthcoming at an increasing rate. To date biochemical studies of otosclerosis have focused on four major tissue constituents: enzymes, components of the bone matrix, hormones, and inorganic constituents of bone.

ENZYMES

Since otosclerosis is a genetically-determined disease, it is likely that the initial biochemical manifestation is either a defective control of the synthesis of an enzyme(s) or the production of a completely or partially non-functional enzyme(s). The biochemical search for aberrant enzyme behaviour was given an impetus by

significant histochemical findings. Albermar & Covell (1961) found large amounts of succinate dehydrogenase and cytochrome oxidase in osteoclasts, fibroblasts, blood vessel walls (and smaller amounts in osteocytes) of otosclerotic foci when compared with control stapedes, suggesting that the former have a high level of respiratory activity. Large concentrations of acid phosphatase have been demonstrated in osteoclasts and in the matrix of otosclerotic bone (Albermar & Covell, 1961). Alkaline phosphatase has been detected both in the cells (osteoblasts, osteoclasts, fibroblasts) and in the otosclerotic matrix (Ricci, 1962; Arslan & Ricci, 1963). Leucine aminopeptidase (Alberti & Tarkannen, 1963) and the non-specific esterase complex (Ardoumi & Wegmann, 1961; Chevanec, Clerc & Bouche, 1962; Alberti & Tarkannen, 1963) have been found in blood vessel walls, perivascular fibroblasts, and particularly in osteocytes close to blood vessels in the otosclerotic foci. Cabrini (1961) however found leucine aminopeptidase activity in the focus to be completely extracellular.

Despite their desirability comparative biochemical studies of enzyme activity in otosclerotic and normal bone are relatively few. Maurer's pioneer study (1961/62) indicated that there is an increase in the total nitrogen content and a decrease in alkaline phosphatase activity in endochondral bone (ossicles, semicircular canal, promontory) from otosclerotics. Maurer concluded that these results were inexplicable on the assumption of an increase in the number or activity of cellular elements (metabolically active) but rather derived from a numerical increase in the fibrils (metabolically inactive). We have carried out comparative studies of extractable protein and certain enzymes (lactate dehydrogenase, malate dehydrogenase, amino aspartic transferase, al-

dolase (glucose-6-phosphate dehydrogenase acid and alkaline phosphatases) in mallei incudes, stapedes (endochondral bone) and in cortical (lamellar) bone from otosclerosis and non-otosclerotic patients (Soifer et al 1967 a b 1969 a) Extractable protein is increased in mallei and incudes and decreased in cortical bone from otosclerotics as compared to normal, while the protein content of stapedes is comparable in otosclerotic and non-otosclerotic patients. Determination of enzyme activities indicate that the overall level of metabolic activity (as measured by the above mentioned enzymes) of both normal and otosclerotic stapedes although not the same, is considerably higher than the metabolic activity of mallei incudes, and cortical bone. One can speculate that this inherently high metabolic rate may be one factor which gives the stapedes their predisposition to the development of foci.

Among the enzymes investigated however only two lactate dehydrogenase and alkaline phosphatase, show statistically significant differences in activity between otosclerotics and non-otosclerotics. In all the samples of bones studied, the activity of lactate dehydrogenase is significantly lowered when otosclerosis is present. Lactate dehydrogenase is 49 percent lower in stapedes, 26 percent lower in cortical bone, and 15 percent lower in mallei and incudes obtained from otosclerotic patients. A particularly striking increase in alkaline phosphatase activity is found in involved stapedes (Soifer et al 1969 a). The average activity in otosclerotic is approximately eight times that in normal stapedes.

Since in whole stapedes the dilution effect of the crura, which usually do not contain foci, is to effectively reduce the magnitude of the observed increase in alkaline phosphatase, we measured the activity of the enzyme in single footplates which were moderately or heavily involved as assessed microscopically. The results appear in Table I.

The values obtained for normal footplates were comparable to those obtained previously for normal whole stapedes (Soifer et al.,

Table I *Alkaline phosphatase activity in stapedial footplates*

Stapedial footplates	Degree of Otosclerosis	Alkaline phosphatase activity ($\times 10^{-4}$ units/min/mg tissue)
1 Otosclerotic	Moderate	13.
2 Otosclerotic	Moderate	37.4
3 Otosclerotic	Heavy	11.6
4 Otosclerotic	Heavy	110.6
5 Normal (labyrinthectomy)	—	3.1
6 Normal (autopsy)	—	6.1
7 Normal (autopsy)	—	1.2
8 Normal (autopsy)	—	3.7

1969 a) Values for involved stapedes were either comparable to or greater than those obtained previously. This would be expected by virtue of elimination of the dilution effect of the crura. These data confirm that there is an increase in alkaline phosphatase activity in otosclerotic bone. There appears to be no consistent correlation between the amount of otosclerotic growth and the level of enzyme activity. However since the footplates were not examined histologically prior to biochemical assay it cannot be assumed that all of the foci present were active. Inactive foci would add to the total amount of otosclerotic growth, but they could also dilute the enzyme activity as do the crura.

The fact that we have observed no change in the concentration of protein but have found a considerable elevation of the alkaline phosphatase activity in involved stapedes suggests that there may be an increase in the cellular metabolic activity of this ossicle in otosclerosis. This conflicts with Maurer's suggestion of a numerical increase in non-metabolic constituents (collagen fibrils) based on his observation of an increased nitrogen content in otosclerotic stapedes. However the fact that in otosclerosis changes (page 14) whatever their nature, are observed in tissues other than those having otosclerotic foci indicates that the biochemical effects of the disease are generalized that is they are not confined to focal areas.

Protein and enzymes in body fluids and in tissues other than bone have been investigated in an effort to measure the extent of such generalized changes. Protein in venous tissue from otosclerotics is lower than normal while lactate dehydrogenase activity is elevated 30 percent above normal (Solfer et al., 1965 a, b). Normal levels of protein (Naumann, 1964) and alkaline phosphatase activity (Fowler 1948; Riskær 1949; Solfer et al., 1965 a) are found in sera from otosclerotics and the serum isoenzyme pattern of alkaline phosphatase shows no abnormal qualitative alterations (Solfer et al., 1963). Other tissues and additional enzymes must be examined in order to assess the total extent of generalized alterations.

THE BONE MATRIX

In addition to the enzymatic changes, the possibility of alterations in the matrix of otosclerotic bone has been investigated. The histochemical evidence indicates that ground substance is active, with large amounts of acid mucopolysaccharide observed in the otosclerotic foci (Albernaz & Covell, 1961). Yet the ground substance of otosclerotic bone appears to be no more or no less active than that of other newly-formed bone (Albernaz & Covell, 1961; Chevance, Clere & Bouche, 1962). The PAS-positive material does vary in density however in different parts of the otosclerotic lesion. This suggests a compositional change, possibly an alteration in the degree of polymerization of the intercellular substance. Perhaps the latter is in a more condensed state and less dynamic.

As mentioned above, the results of Maurer's biochemical study (1961: 62) indicate an increase in the fibrillar content of otosclerotic bone. Yet, under the polarizing microscope the collagenous matrix of the focus (irregularly arranged fibrils) is similar to that of other newly formed fibrous bone (Cabrini, 1961; Albert & Tarkannen, 1963) but different from that of normal endochondral bone (the fibrils are arranged in a more orderly pattern). This suggests that otosclerotic changes in the fibrils,

as well as in the ground substance, may be organizational rather than absolute. The cells of the focus may be abnormally immature so that only eventually and slowly is the immature matrix remodeled into typical lamellar Haversian bone (Cabrini, 1961). The demonstration of leucine aminopeptidase activity in the newly-formed ground substance theoretically supports this idea, as it is postulated that the presence of this enzyme is indicative of immature fibrous tissue, especially immature fibroblasts, and may function in the formation of collagen fibrils. With the electron microscope, interwoven collagenous bundles are seen intricately arranged but here the collagen matrix of the otosclerotic focus appears denser than that of normal fibrous bone (Chevance et al., 1969). This would appear to support Maurer's postulated numerical increase in fibrils.

In our investigation of the matrix of otosclerotic bone, we measured hexosamine, and hydroxyproline and proline (indices of total mucopolysaccharide and total collagen, respectively) in ossicles and samples of bone from other regions of the otic capsule and found no abnormal changes in tissue from otosclerotics (Solfer et al., 1969 d). There are inherent regional differences in the hexosamine content of the otic capsule bone e.g., the highest amount is found in stapedial footplates, followed by crura, promontory semicircular canal capsule, round and oval window mallei, heads of mallei, incudes, and cortical bone, in that order. But we found no correlation between the regional variations and the frequency of occurrence of otosclerotic foci. Although the total mucopolysaccharide in otosclerotics does not appear to be altered, it is conceivable that differences may occur in the proportions of the specific types of mucopolysaccharide molecules (the relative amounts of acid, neutral, sulfated, and non-sulfated mucopolysaccharides may change) as well as in the degree of their polymerization. The histochemical finding of increased acid mucopolysaccharide in active foci may also be valid biochemically. This, of course would presuppose a decrease in neutral

mucopolysaccharide in order that the total remain unchanged

The constancy of the ratio of hydroxyproline to proline in all samples investigated suggests that intermolecular differences in the fibrillar content do not occur as a result of otosclerosis (Soifer et al 1969 *d*). However this does not rule out differences in fibrillar organization which may well exist. The question of whether there is or is not a numerical increase in collagen fibrils in otosclerosis remains at present, unresolved.

Efforts have been made to determine if changes attributed to otosclerosis occur in the matrices of tissues other than bone and, in the event that such changes do occur if they are reflected in urinary excretory products. An increase in the amount of ground substance in the corium of the skin as well as a decrease in the number of fine collagen fibers and an increase in the number of elastic fibers is reported by Vyalonzi (1965), Bentzen (1961) and Stadil (1961). However biochemical analysis of the total mucopolysaccharide and total acid mucopolysaccharide fractions of vein revealed no differences between otosclerotics and non-otosclerotics (Soifer et al 1969 *d*). Thus far the number of studies devoted to investigating generalized changes is too small to provide a basis of valid assessment. However indications are that if such generalized changes do occur they are not reflected in the products of urinary excretion of amino acids (and by inference collagen) and hexosamine in otosclerotic patients and found no variations from normal. Similarly we found urinary acid mucopolysaccharide excretion to be the same in otosclerotics and non-otosclerotics (Soifer et al 1969 *e*). In addition, electrophoretic separation showed a similar migratory distribution of urinary mucopolysaccharides.

HORMONES

The dynamic processes of bone turnover affect both mineral and organic constituents. Normal ly collagen is only slightly subject to turnover

It must, however be replaced after resorption such as occurs in otosclerosis. It is currently theorized that physiological replacement and resorption are under hormonal control, specifically that the sex hormones, androgens and estrogens provide the stimulus for replacement while the adrenocortical hormones activate resorption (McLean & Urst, 1961). Under normal physiological conditions there exists a balance between resorption and replacement of the matrix. If this view is accepted, it follows that the pathological resorption and replacement processes of otosclerosis might reflect a hormonal imbalance.

Certain clinical observations of the pathogenesis and progress of otosclerosis are indicative of the involvement of hormones. The onset of otosclerotic deafness frequently coincides with puberty and the incidence of onset increases with age (Wullstein, 1960; Larsson, 1960). Since however the disease is histologically detectable long before it is clinically manifest (Larsson, 1960) the implication is that hormones may in some way enhance the progress of the disease. This is supported by the observation that otosclerotic deafness seems more severe during pregnancy. It is, of course, possible that this enhancement effect is only apparent since the patient normally has a heightened consciousness of body functions during this period.

The principal experimental approach toward ascertaining the significance of hormones in the pathogenesis of otosclerosis has been the measurement of levels of urinary steroids. However studies of this type are few in number and results do not always agree. Herrmann & Maurer (1955) reported decreased levels of urinary androgens in otosclerotic patients, while Vyalonzi & Klein (1961) found these levels to be normal. An increase in the level of urinary estrogens in otosclerotic patients particularly in males aged 20 to 50 years, has been reported (Vyalonzi & Klein, 1961; Vyalonzi 1963). More recently however DeJorge and co-workers (1965) found normal levels of estrogens in otosclerotics (both males and females). Changes in the amounts of 17 ketosteroids

In otosclerotic patients were reported by Maggio (1953) and by Herrmann & Maurer (1955). But Vyskonzil & Klein (1961) found nine out of fourteen male otosclerotic patients to have 17-ketosteroid levels in the normal range. This result is substantiated by our more extensive studies (Soifer et al 1969) in preparation) which also shows the excretion of 17-hydroxy-steroids to be normal in otosclerotics.

The conflicting results leaving from the various studies preclude, at present, even a hypothetical evaluation of the specific function(s) of hormones in the pathogenesis of otosclerosis. That hormones are involved appears certain merely by virtue of their ubiquitous influence on physiological processes in general and the clinically-observed enhancement of otosclerosis by puberty and pregnancy. Otosclerosis does result from an upset in the normal dynamic equilibrium between resorption and accretion of bone. However it is also true that accretion in otosclerosis consists in deposition of pathological fibrous bone and thus cannot merely result from an upset in normal physiological activity. Therefore, a simple change in the relative levels of the sex and adrenocortical hormones, if these do indeed control resorption and accretion, cannot alone account for the pathogenic process but rather may be one of several contributing factors.

INORGANIC CONSTITUENTS

Because of the fundamental relationship of minerals and ions to bone, investigations have been directed toward determining if pathological changes in the inorganic constituents of the matrix occur as a result of otosclerosis. If only because otosclerotic bone resembles immature fibrous bone, one would expect incomplete mineralization (Frost, 1962). The radiological picture of cochlear foci supports this hypothesis (Derback & Valvasor, 1965). Recently the total mineral content of one malleus and several incudes obtained from otosclerotics was investigated by a technique based on measurement of bone density i.e. monoenergetic photon

beam transmission (Evans & Henkin, 1969). As the authors indicate, evaluation of the findings is severely restricted by the lack of a sufficient number of samples, among other things. But the limited data are indicative of a lower than normal mean mineral content in mallei and incudes from otosclerotics. If further studies confirm this tentative result, alterations in the mineral content of the matrix of uninvolved bone could be included among the "generalized changes" caused by otosclerosis.

In addition to studies of total mineral content, individual elements and ions have been investigated in bone and serum from otosclerotics. The results of several studies appear in Table II. It is evident that agreement among studies is the exception. Methodology appears to be a significant factor in the conflict. For example, Maurer's biochemical technique demonstrated a lower than normal calcium and phosphorus content in stapedes from otosclerotics while the neutron activation analysis that we used yielded values comparable to those for normal stapedes. The conflicting results give rise to alternate interpretations of the state of mineralization of otosclerotic bone. Maurer's results indicate that mineralization is incomplete and, coupled with data pointing to an increased fibrillar content, suggest that an altered apatite:fibril relationship characterizes otosclerotic bone. Our results do not deny the existence of such compositional change but suggest that it may consist purely of differences in the structural relationship among the components of the matrix rather than of absolute changes in the total amount of individual minerals or of fibrils. Further analyses will perhaps resolve the conflict. However it cannot be denied that the ultrasensitivity of neutron activation analysis (quantities can be detected in a range of 0.1 to 100 µg per sample) coupled with the requirement for minimal amounts of tissue (fractions of milligrams) make it a most valuable and accurate method for quantitative measurement of minerals and other elements in bone.

At best, quantitative measurement of elements in otosclerotic bone indirectly reflect a women-

mucopolysaccharide in order that the total remain unchanged.

The constancy of the ratio of hydroxyproline to proline in all samples investigated suggests that intermolecular differences in the fibrillar content do not occur as a result of otosclerosis (Soifer et al 1969 d) However this does not rule out differences in fibrillar organization which may well exist. The question of whether there is or is not a numerical increase in collagen fibrils in otosclerosis remains at present, unresolved.

Efforts have been made to determine if changes attributed to otosclerosis occur in the matrices of tissues other than bone and in the event that such changes do occur if they are reflected in urinary excretory products. An increase in the amount of ground substance in the corium of the skin as well as a decrease in the number of fine collagen fibers and an increase in the number of elastic fibers is reported by Vyslonzil (1965) Bentzen (1961) and Stadil (1961) However biochemical analysis of the total mucopolysaccharide and total acid mucopolysaccharide fractions of vein revealed no differences between otosclerotics and non-otosclerotics (Soifer et al 1969 d) Thus far the number of studies devoted to investigating generalized changes is too small to provide a basis of valid assessment. However indications are that if such generalized changes do occur they are not reflected in the products of urinary excretion of amino acids (and by inference collagen) and hexosamine in otosclerotic patients and found no variations from normal. Similarly we found urinary acid mucopolysaccharide excretion to be the same in otosclerotics and non-otosclerotics (Soifer et al 1969 e) In addition, electrophoretic separation showed a similar migratory distribution of urinary mucopolysaccharides.

HORMONES

The dynamic processes of bone turnover affect both mineral and organic constituents. Normal collagen is only slightly subject to turnover

It must, however, be replaced after resorption such as occurs in otosclerosis. It is currently theorized that physiological replacement and resorption are under hormonal control specifically that the sex hormones, androgens and estrogens, provide the stimulus for replacement while the adrenocortical hormones activate resorption (McLean & Urist, 1961) Under normal physiological conditions there exists a balance between resorption and replacement of the matrix. If this view is accepted, it follows that the pathological resorption and replacement processes of otosclerosis might reflect a hormonal imbalance.

Certain clinical observations of the pathogenesis and progress of otosclerosis are indicative of the involvement of hormones. The onset of otosclerotic deafness frequently coincides with puberty and the incidence of onset increases with age (Wullstein, 1960; Larsson, 1960). Since however the disease is histologically detectable long before it is clinically manifest (Larsson, 1960) the implication is that hormones may in some way enhance the progress of the disease. This is supported by the observation that otosclerotic deafness seems more severe during pregnancy. It is, of course, possible that this enhancement effect is only apparent since the patient normally has a heightened consciousness of body functions during this period.

The principal experimental approach toward ascertaining the significance of hormones in the pathogenesis of otosclerosis has been the measurement of levels of urinary steroids. However studies of this type are few in number and results do not always agree. Herrmann & Maurer (1955) reported decreased levels of urinary androgens in otosclerotic patients, while Vyslonzil & Klein (1961) found these levels to be normal. An increase in the level of urinary estrogens in otosclerotic patients, particularly in males aged 20 to 50 years, has been reported (Vyslonzil & Klein 1961; Vyslonzil 1963). More recently however DeJorge and co-workers (1965) found normal levels of estrogens in otosclerotics (both males and females). Changes in the amounts of 17 ketosteroids

in which it is scientifically economical to proceed

All theories of the etiology of osteosclerosis must ultimately center on the osteoid cell, in one or other of its forms, and on its deposition of intercellular material. Classically osteoblasts have been implicated in the initial deposition of bone osteocytes, in its maintenance osteoclasts, in its resorption. However the transformation of these three types of cells one into another and their ultimate common derivation from mesenchymal cells causes difficulties in determining the complement of activities which each performs and the division of labor between them, the latter possibly being less well-defined than originally supposed. Thus, any information that can be obtained about both the normal and abnormal physiology of these cells would be of immense value to research in osteosclerosis. Tissue culture appears to be a logical and beneficial approach. Lawrence (1965) has been successful in isolating and growing osteoblasts from osteosclerotic bone in tissue culture, but attempts at subculture have failed.

The crux of the problem of osteosclerosis is the resorption of normal bone and the deposition of immature fibrous bone in areas to which the latter is normally foreign. How are osteoid cells stimulated to destroy the existing bone structure and subsequently to lay down this fibrous bone? And which of the various osteoid cells is responsible?

With respect to the second of these questions, the resorptive role has been variously attributed to the osteoclast and the osteocyte. As previously mentioned the latter has traditionally been assumed to participate in maintenance and turnover. But other evidence suggests that the osteocyte can resorb bone as well (Sognnaes, 1963). In electron micrographs of osteosclerotic foci made by Chevance and co-workers (1969), lysins of collagen in the vicinity of osteocytes is invariably present, and, significantly lysosomes occur within the osteocyte. Since the hydrolytic enzymes contained in lysosomes can dissociate proteins, the simultaneous occurrence of these

Table III Acid phosphatase activity in stapedial footplates

Stapedial footplate	Degree of Osteosclerosis	Acid phosphatase activity ($\times 10^{-4}$ p. moles/min./mg. tissue)
1 Osteosclerotic	Moderate	14.2
2 Osteosclerotic	Moderate	17.2
3 Osteosclerotic	Heavy	32.1
4 Osteosclerotic	Heavy	36.8
5 Normal (autopsy)	—	11.6
6 Normal (autopsy)	—	10.1
7 Normal (autopsy)	—	10.8

structures with pericellular lysis of collagen strongly implicates the osteocyte in the bone resorption which characterized the initial stage of osteosclerosis. It is significant that large amounts of acid phosphatase (contained in lysosomes) have been detected histochemically in the matrix of osteosclerotic foci (Albernaz & Coveil, 1961). However the enzyme has also been found in large quantities in osteoclasts as well as in the bone matrix (Albernaz & Coveil, 1961) and to this apparent contradiction we shall later return.

Recently we used biochemical techniques to measure acid phosphatase activity in osteosclerotic and non-osteosclerotic stapedial foot plates. The results appear in Table III. Since the assays were carried out on intact bone, the proportion of acid phosphatase activity contributed by the matrix as opposed to cells could not be determined. However the biochemical findings confirm that increased acid phosphatase activity characterizes osteosclerotic tissue and, significantly that the level of activity is correlated with the degree of osteosclerotic growth.

The postulated role of lysosomes in the resorptive process in osteosclerosis is supported by evidence of their function in physiological resorption. Chevance and co-workers (1969) point out that Vaes (1965) demonstrated the release of lysosomal enzymes into tissue culture medium from bone cells undergoing parathyroid hormone-induced resorption. In tissue cultures

tary balance between the dynamic processes of resorption and accretion. An absolute increase or decrease in mineral content merely indicates that accretion or resorption respectively is dominant in the focus at the time of analysis. Measurement of turnover rates of individual element would seem a logical approach toward investigating possible abnormalities in the rates of dynamic processes which might lead to pathological structural alterations.

Maurer's results indicating a lower than normal calcium and phosphorus content in endochondral bone (mallel, incudae, semicircular canal promontory) from otosclerotics are in agreement with those of the above mentioned photon beam study. They support the idea that alterations in elemental composition may be included among the "generalized" pathological ramifications of otosclerosis. Various ions in serum have been investigated with an eye to determining the extent of such generalized changes. But as is evident from Table II, conflicting results have but added additional pieces to the puzzle.

THE PRESENT STATE OF RESEARCH

The present state of research in otosclerosis appears to these authors to be one of productive confusion. The varied approaches to the problem are building a foundation of data upon which a somewhat shaky superstructure of theory is precariously balanced. It is advantageous for the solution of the problem that attacks are being made on so many fronts. It has, however, given rise to innumerable theories of the etiology of otosclerosis, none of which attempts to integrate the findings of other approaches. This state of affairs can be viewed in two lights. It is admirably scientific to be always aware of the limitations of one's discipline in order that foolish and misleading indiscretions of thought not be committed. But it is also both desirable and beneficial, if only for pinpointing inconsistencies, that some attention be devoted to consolidating, assessing, and placing in perspective the experimental data amassed from the various disciplines. One would hope that a bit of reflection might suggest fruitful avenues for further experimentation as well as the general direction

in which it is scientifically economical to proceed

All theories of the etiology of osteosclerosis must ultimately center on the osteoid cell, in one or other of its forms, and on its deposition of intercellular material. Classically osteoblasts have been implicated in the initial deposition of bone; osteocytes, in its maintenance; osteoclasts, in its resorption. However the transformation of these three types of cells one into another and their ultimate common derivation from mesenchymal cells causes difficulties in determining the complement of activities which each performs and the division of labor between them, the latter possibly being less well-defined than originally supposed. Thus, any information that can be obtained about both the normal and abnormal physiology of these cells would be of immense value to research in osteosclerosis. Tissue culture appears to be a logical and beneficial approach. Lawrence (1965) has been successful in isolating and growing osteoblasts from osteosclerotic bone in tissue culture, but attempts at subculture have failed.

The crux of the problem of osteosclerosis is the resorption of normal bone and the deposition of immature fibrous bone in areas to which the latter is normally foreign. How are osteoid cells stimulated to destroy the existing bone structure and subsequently to lay down this fibrous bone? And which of the various osteoid cells is responsible?

With respect to the second of these questions, the resorptive role has been variously attributed to the osteoclast and the osteocyte. As previously mentioned, the latter has traditionally been assumed to participate in maintenance and turn over. But other evidence suggests that the osteocyte can resorb bone as well (Sognnaes, 1963). In electron micrographs of osteosclerotic foci made by Chevance and co-workers (1969) lysis of collagen in the vicinity of osteocytes is invariably present and, significantly, lysosomes occur within the osteocyte. Since the hydrolytic enzymes contained in lysosomes can dissociate protein, the simultaneous occurrence of these

tary balance between the dynamic processes of resorption and accretion. An absolute increase or decrease in mineral content merely indicates that accretion or resorption, respectively is dominant in the focus at the time of analysis. Measurement of turnover rates of individual element would seem a logical approach toward investigating possible abnormalities in the rates of dynamic processes which might lead to pathological structural alterations.

Maurer's results indicating a lower than normal calcium and phosphorus content in endochondral bone (mallel incudes, semicircular canal promontory) from otosclerotics are in agreement with those of the above mentioned photon beam study. They support the idea that alterations in elemental composition may be included among the "generalized" pathological ramifications of otosclerosis. Various ions in serum have been investigated with an eye to determining the extent of such generalized changes. But as is evident from Table II conflicting results have but added additional pieces to the puzzle.

THE PRESENT STATE OF RESEARCH

The present state of research in otosclerosis appears to these authors to be one of productive confusion. The varied approaches to the problem are building a foundation of data upon which a somewhat shaky superstructure of theory is precariously balanced. It is advantageous for the solution of the problem that attacks are being made on so many fronts. It has, however given rise to innumerable theories of the etiology of otosclerosis, none of which attempts to integrate the findings of other approaches. This state of affairs can be viewed in two lights. It is admirably scientific to be always aware of the limitations of one's discipline in order that foolish and misleading indiscretions of thought not be committed. But it is also both desirable and beneficial, if only for pinpointing inconsistencies, that some attention be devoted to consolidating, assessing, and placing in perspective the experimental data amassed from the various disciplines. One would hope that a bit of reflection might suggest fruitful avenues for further experimentation as well as the general direction

in which it is scientifically economical to proceed.

All theories of the etiology of osteosclerosis must ultimately center on the osteoid cell, in one or other of its forms, and on its deposition of intercellular material. Classically osteoblasts have been implicated in the initial deposition of bone osteocytes, in its maintenance osteoclasts, in its resorption. However the transformation of these three types of cells one into another and their ultimate common derivation from mesenchymal cells causes difficulties in determining the complement of activities which each performs and the division of labor between them, the latter possibly being less well-defined than originally supposed. Thus, any information that can be obtained about both the normal and abnormal physiology of these cells would be of immense value to research in osteosclerosis. Tissue culture appears to be a logical and beneficial approach. Lawrence (1965) has been successful in isolating and growing osteoblasts from osteosclerotic bone in tissue culture, but attempts at subculture have failed.

The crux of the problem of osteosclerosis is the resorption of normal bone and the deposition of immature fibrous bone in areas to which the latter is normally foreign. How are osteoid cells stimulated to destroy the existing bone structure and subsequently to lay down this fibrous bone. And which of the various osteoid cells is responsible?

With respect to the second of these questions, the resorptive role has been variously attributed to the osteoclast and the osteocyte. As previously mentioned, the latter has traditionally been assumed to participate in maintenance and turnover. But other evidence suggests that the osteocyte can resorb bone as well (Sognnaes, 1963). In electron micrographs of osteosclerotic foci made by Chevance and co-workers (1969), lysis of collagen in the vicinity of osteocytes is invariably present, and, significantly lysosomes occur within the osteocyte. Since the hydrolytic enzymes contained in lysosomes can dissociate protein, the simultaneous occurrence of these

Table III. Acid phosphatase activity in stapedial footplates

Stapedial footplates	Degree of Osteosclerosis	Acid phosphatase activity ($10^{-4} \mu$ moles/min/mg tissue)
1 Osteosclerotic	Moderate	14.2
2 Osteosclerotic	Moderate	17.2
3 Osteosclerotic	Heavy	32.1
4 Osteosclerotic	Heavy	36.8

structures with pericellular lysis of collagen strongly implicates the osteocyte in the bone resorption which characterized the initial stage of osteosclerosis. It is significant that large amounts of acid phosphatase (contained in lysosomes) have been detected histochemically in the matrix of osteosclerotic foci (Albermarz & Covell, 1961). However the enzyme has also been found in large quantities in osteoclasts as well as in the bone matrix (Albermarz & Covell, 1961) and to this apparent contradiction we shall later return.

Recently we used biochemical techniques to measure acid phosphatase activity in osteosclerotic and non-osteosclerotic stapedial footplates. The results appear in Table III. Since the assays were carried out on intact bone the proportion of acid phosphatase activity contributed by the matrix as opposed to cells could not be determined. However the biochemical findings confirm that increased acid phosphatase activity characterizes osteosclerotic tissue and, significantly that the level of activity is correlated with the degree of osteosclerotic growth.

The postulated role of lysosomes in the resorptive process in osteosclerosis is supported by evidence of their function in physiological resorption. Chevance and co-workers (1969) point out that Vace (1965) demonstrated the release of lysosomal enzymes into tissue culture medium from bone cells undergoing parathyroid hormone-induced resorption. In tissue cultures

of embryonic cells, lysosomes can be stimulated to swell and rupture, thus releasing their contents, by simply oxygenating the culture (Sledge, 1965). It would appear to be significant that hyperaemia is an invariable condition in active otosclerotic foci. Thus the theory is presented by Chevance and co-workers (1969) that the primary factor in the development of the otosclerotic focus is a basic alteration in the osteocyte resulting in the swelling and rupture of its lysosomes. The latter by virtue of release of proteolytic enzymes, causes dissolution of the osteocyte and of the surrounding collagen fibrils.

Since the osteoclast traditionally has been implicated in physiological resorption of bone and because of the presence of numerous osteoclasts in areas of otosclerotic resorption the hypothesis logically developed that the osteoclast was responsible for the resorptive processes in the initial stage of the disease. No weak support was lent to this idea by the above mentioned discovery of intraosteoclastic acid phosphatase. However, Chevance and co-workers (1969) were unable to find evidence of activity (intracellular lysosomes and pericellular lysis of collagen) in any osteoclast observed under the electron microscope. The role of the osteoclast may merely be phagocytic, a suggestion often forwarded but still lacking complete experimental substantiation. During physiological resorption, osteoclasts exhibit intense succinate dehydrogenase and cytochrome oxidase activity while osteoblasts show only mild activity if any (Burstone, 1960 a, b). An identical situation is found in otosclerotic resorption. Albernaz & Covell (1961) find the activities of these enzymes to be intense in osteoclasts but mild or non-existent in osteocytes. This high level of oxidative activity would be expected were the cell engaged in active phagocytosis. And given the amount of acid phosphatase released into the matrix of the bone being resorbed, it would not be unusual to detect the enzyme within the osteoclasts as the latter engulfed remnants of the disintegrating matrix. Finally, because osteoclasts in otosclerotic foci exhibit no mor-

phological or histochemical abnormalities, i.e. their appearance and activities are identical to those in physiological resorptive centers, it would seem unlikely that they are primary in pathogenesis of the disease.

The evidence which has accumulated for the primary role of the osteocyte in resorption at least hypothetically answers the second of our two questions. The first namely how are osteocytes stimulated to initiate resorption and subsequently to lay down fibrous bone is a considerably greater puzzle. Regarding the initiation of resorption, a consideration which merits further attention is the above mentioned hyperaemia which is invariably present in active foci. The fact that osteocytes are clustered around blood vessels in the focus (Alberti & Tarkannen 1963) may be significant.

The deposition of fibrous bone following resorption however appears to result from an alteration in enzyme activity in the osteocyte. The enzymes which have been detected histochemically and/or biochemically in the focus are normally present in bone but the activities of certain of these, i.e. lactate dehydrogenase and alkaline phosphatase are unlike those in uninvolved bone. The decreased activity of lactate dehydrogenase in involved stapedes (Solfer et al. 1969 a) may be linked with the increased quantity of free sulfhydryl groups found in the otosclerotic lesion (Chevance, 1965). Perhaps the enzyme is in some way depolymerized to yield subunits which are inactive. Alternatively the hyperaemia characteristic of active foci may be indicative of a hyperactive respiratory cycle. The latter could cause the observed decrease in lactate dehydrogenase activity via feedback inhibition.

The role of alkaline phosphatase in otosclerosis would appear to be particularly significant for two reasons. First, the experimental data show that it is present in large amounts in active foci (Arafan & Ricci 1963; Chevance, 1965; Solfer et al., 1969 a). Second it is generally accepted that alkaline phosphatase functions in the formation of the normal bone matrix. The enzyme is implicated in the pro-

duction of collagen fibrils. Newman (1956) proposed that phosphate esters, synthesized inside the cell, may be secreted at the cell surface where they are dephosphorylated by extracellular alkaline phosphatase and combine to form fibrils. This would explain the presence of the enzymes in the newly-formed matrix immediately prior to the deposition of bone salts as well as at fibrogenic sites. Alternatively or additionally alkaline phosphatase may function in the synthesis of the mucopolysaccharides of the ground substance. Kroon (1952) suggested that the enzyme may provide the units necessary for mucopolysaccharide synthesis by liberating the former from the hexose phosphate esters produced during glycolytic breakdown. A full and precise characterization of the role assumed by alkaline phosphatase in the pathogenesis of otosclerosis must await clarification of the physiological role of the enzyme as well as detailed definition of the changes in the matrix caused by the disease process.

FUTURE RESEARCH

Similarly the nature of the relationship between decreased lactate dehydrogenase activity and increased alkaline phosphatase activity has yet to be determined. Glycolytic substrates such as glucose-6-phosphate and D-glucosamine-6-phosphate are rapidly hydrolysed by non-

specific alkaline phosphatase. The use of substrates labelled with ^{14}C and/or ^{32}P and the simultaneous determination of the activities of lactate dehydrogenase and alkaline phosphatase would seem a useful approach toward investigation of the functional relationship of the two enzymes.

Since evidence indicates that the content of collagen in otosclerotic bone is normal, turnover should be studied. The amount of bone present at any time is a result of two separate processes, resorption and accretion. Since otosclerosis results in an increase in the amount of bone (in stapes fixation) which appears to have a normal chemical matrix and inorganic composition, the equilibrium between the two processes must be altered in favor of accretion. Therefore, an investigation of this equilibrium by determination of absorption and accretion of the collagen matrix would provide relevant information.

Further there is positive evidence (the previously mentioned aberrations in mallel, incus, cortical bone, and vein see page 14) that otosclerosis may be a localized manifestation of a more generalized condition. Biochemical investigations in search of other aberrations in tissues, even those remotely located (for example, long bones) could conceivably be the approach most likely to be the key to the problem of otosclerosis.

I Introduction and Purpose

Normal development of body form is dependent upon the synchronous coordination of the activities of the growth sites of the skeleton and related structures (1). Any interference which alters the orderly progression of development results in faulty growth. The subsequent deformity may vary and depends not only upon the type, intensity, extent, and chronology of the noxious agent, but also upon the susceptibility and growth activity of the particular site. Trauma to endochondral growth centers can result in marked bony deformities. This is in contrast to the effects of trauma to regions of sutural or appositional (periosteal, endosteal) growth of bones (2).

The septovomer region is considered an important growth center (3, 4). The relationship of trauma to this region to nasal and facial development is of clinical interest. A group of experiments was designed to test the effects upon growth of the face of varying degrees of surgical resection and trauma to different parts of the septovomer region in both the growing and adult rabbit (5-11). The information obtained is reviewed and summarized in this report in relation both to basic concepts of growth of bones and to possible clinical significance.

II Review of the Literature

Hilton (3) in 1845 described the role of the vomer in the downward and forward growth of the maxillae and the deepening of the nasal fossae. Fick (12) in 1858 removed a portion of the cartilaginous nasal septum through a trephine opening of the nasal bones in growing dogs, cats, pigs, and goats. At autopsy the hard palate was greatly shortened anteroposteriorly and he stated that growth of the hard palate was dependent upon the growth of the nasal septum. Landsberger (13) in 1929 re-

sected in part the anterior portion of the septum in dogs 2 weeks of age, killed them 6 months later and found that the anterior part of the floor of the nasal cavity was higher than normal. He concluded that the growing septum was an important factor in pushing the floor of the nasal cavity downward. Selman & Sarnat reported that although the frontonasal suture was a site of rapid growth (14), its extirpation in the rabbit failed to produce a growth arrest of the snout (15).

III Brief Description of the Osteology of the Rabbit Face

The rabbit face is comprised, in part, of the mandibular premaxillary maxillary and nasal bones (Fig. 1).

The nasal cavity communicates posteriorly with the ventral surface of the skull by the choanae which, in the rabbit, are incompletely

I Introduction and Purpose

Normal development of body form is dependent upon the synchronous coordination of the activities of the growth sites of the skeleton and related structures (1). Any interference which alters the orderly progression of development results in faulty growth. The subsequent deformity may vary and depends not only upon the type, intensity, extent, and chronology of the noxious agent, but also upon the susceptibility and growth activity of the particular site. Trauma to endochondral growth centers can result in marked body deformities. This is in contrast to the effects of trauma to regions of sutural or appositional (periosteal, endosteal) growth of bones (2).

The septovomer region is considered an important growth center (3, 4). The relationship of trauma to this region to nasal and facial development is of clinical interest. A group of experiments was designed to test the effects upon growth of the face of varying degrees of surgical resection and trauma to different parts of the septovomer region in both the growing and adult rabbit (5-11). The information obtained is reviewed and summarized in this report in relation both to basic concepts of growth of bones and to possible clinical significance.

II Review of the Literature

Hilton (3) in 1845 described the role of the vomer in the downward and forward growth of the maxillae and the deepening of the nasal fossae. Fick (1) in 1858 removed a portion of the cartilaginous nasal septum through a trephine opening of the nasal bones in growing dogs, cats, pigs, and goats. At autopsy the hard palate was greatly shortened anteroposteriorly and he stated that growth of the hard palate was dependent upon the growth of the nasal septum. Landsberger (13) in 1929 re-

sected in part the anterior portion of the septum in dogs 2 weeks of age, killed them 6 months later and found that the anterior part of the floor of the nasal cavity was higher than normal. He concluded that the growing septum was an important factor in pushing the floor of the nasal cavity downward. Selman & Samat reported that although the frontonasal suture was a site of rapid growth (14), its extirpation in the rabbit failed to produce a growth arrest of the snout (15).

III Brief Description of the Osteology of the Rabbit Face

The rabbit face is composed, in part, of the mandibular premaxillary maxillary and nasal bones (Fig. 1).

The nasal cavity communicates posteriorly with the ventral surface of the skull by the choanae which, in the rabbit, are incompletely

I Introduction and Purpose

II Review of the Literature

Hilton (3) in 1845 described the role of the vomer in the downward and forward growth of the maxillae and the deepening of the nasal fossae. Fick (12) in 1858 removed a portion of the cartilaginous nasal septum through a trephine opening of the nasal bones in growing dogs, cats, pigs, and goats. At autopsy the hard palate was greatly shortened anteroposteriorly and he stated that growth of the hard palate was dependent upon the growth of the nasal septum. Landsberger (13) in 1979 re-

sected in part the anterior portion of the septum in dogs 2 weeks of age, killed them 6 months later and found that the anterior part of the floor of the nasal cavity was higher than normal. He concluded that the growing septum was an important factor in pushing the floor of the nasal cavity downward. Selman & Sarnat reported that although the frontonasal suture was a site of rapid growth (14), its extirpation in the rabbit failed to produce a growth arrest of the snout (15).

III Brief Description of the Osteology of the Rabbit Face

The rabbit face is comprised, in part, of the mandibular premaxillary maxillary and nasal bones (Fig. 1).

The nasal cavity communicates posteriorly with the ventral surface of the skull by the choanae which, in the rabbit, are incompletely

Fig 1 Photographs of normal adult rabbit cranium. A dorsal B ventral C frontal, D lateral views. F frontal bone FN frontonasal suture FP frontal process of premaxilla, I labial incisor, l lingual incisor IF incisive foramen IS internasal suture M

teriorly the ventral portion of the cartilaginous nasal septum is supported by and rests in a dorsal groove of a vertical bony plate, the vomer. This forms the septovomer joint. The vomer a median, somewhat sickle-shaped vertical plate of bone separates the ventral portions of the nasal fossae. Anteriorly the nasal septum bears on its ventral margin, the paired enclosures of the vomeronasal organ. The septal cartilage extends anteriorly to the piriform aperture and terminates above the basal

portion of the incisors (Figs. 2A and 13). Information is meager on postnatal growth of the cartilaginous nasal septum (17-18). Normal levels of proliferative cellular activity in the young rabbit cartilaginous nasal septum were determined by autoradiographic studies with tritiated thymidine (18A). Cellular activity was most pronounced in the anteroinferior and posterior zones (Fig. 3). The cartilaginous nasal septum exhibited an independent growth potential in organ culture (18B).

divided (16) Anteriorly it opens to the outside by the piriform aperture

Bilateral division is effected chiefly through a median vertical cartilaginous plate the nasal septum (Fig. 2) This is continuous postero-

superiorly as a synchondrosis with a small crescentic vertical plate of bone the perpendicular plate of the ethmoid bone and posteriorly with the presphenoid Both are sites of endochondral bone formation Inferopos-

foramen on the medial surface immediately behind the last molar.

The body of the mandible bears on its dorsal margin the alveoli of an incisor anteriorly and of the premolars and molars posteriorly (Figs. 10 E and 16 A). The alveolar process of each premaxilla contains a larger labial and a smaller lingual incisor (Figs. 1 and 10 E). The alveolar process of each maxilla contains the premolars and molars. The double set of upper incisors and three upper premolars distinguish the rabbit as a lagomorph from the rodent. The upper incisor occludes labial to the lower one and represents a larger segment of a smaller

spiral (Fig. 10 E). The lower incisor although larger than the upper one, represents a smaller segment of a larger spiral. While the incisors in the rabbit are continuously growing and erupting, they are worn at the edges and thereby maintain occlusion. Because of the thicker layer of enamel on the labial surface and the thinner layer of enamel and softer dentin on the lingual surface there is a differential in wear thus producing a sharp bevel. Whereas the basal end of the lower incisor extends to the premolar the basal end of the upper incisor is considerably anterior to the premolar (Fig. 10 E).

IV Materials and Methods

A Animals

Different experiments were designed to determine the effects of varying amounts of surgical resection and trauma to the septovomer region in five groups of growing and one group of adult New Zealand albino rabbits (Table I). Additional rabbits served as operated and unoperated controls. The rabbit was selected because of the rapid increase in length of the snout.

B Anesthesia

A solution of 1 per cent procaine hydrochloride (0.5 to 2 cc) was injected submucosally in the sulcus between the upper incisors and lip. The adult rabbits first were injected intramuscularly with pentobarbital sodium (30 mg/kg) and propiomedazine hydrochloride (Trauvel) (7.5 mg/kg).

C. Surgical Procedure

The animals were secured on an operating board in the supine position. The face and snout were cleansed with an antiseptic solution. An approximately 1.5 cm transverse incision was made through the mucosa between

the upper incisors and the lip. The tissues were elevated from the premaxilla, entrance was gained into the nasal cavity and the septum and septovomer joint were exposed. This was the extent of the surgical procedure for the animals which served as operated on controls.

In one experimental group of growing animals the inferior border of the cartilaginous nasal septum was mobilized, by lifting it out of the vomerine groove, and completely dislocated laterally (6). No tissue was resected. In a second group of growing rabbits central septal cartilage and mucous membrane sections ranging from 3 to 6 mm in width and 9 to 15 mm in length were resected with preservation of the surrounding borders (8). In a third group of growing animals maximum amounts of the anterior portion and body of the cartilaginous nasal septum including mucoperichondrium were resected (7). The vomer was left intact. A similar procedure was followed in a group of adult rabbits (9). In a final group of growing rabbits, cartilaginous nasal septum, vomer and premaxilla were removed (5). The mucosal wound margins were approximated and sutured with no 4-0 black silk. These animals, except for the one experiment with adult rabbits, were operated on at 2 to 7 weeks

Fig 3 Diagrammatic representation of a longitudinal section of the cartilaginous nasal septum of a 3 week-old Dutch rabbit after intraperitoneal injection of tritiated thymidine. The various zones are numbered according to their relative activity (labeling

index, zone 1 3.36 zone 32, 0.35%). Antero-inferior and posterior areas (heavily outlined) were the most active. Cell counts were made of the stippled areas. (From Long, R., Greulich, R., and Sarnat, B. G. J Dent Res., 47 505 1968)

The thin and elongated nasal bone forms the roof of the nasal fossa, and in conjunction with its fellow of the opposite side, the dorsal boundary of the piriform aperture (Fig. 1 A). The posterior border of the nasal bone articulates with the anterior border of the frontal bone forming the frontonasal suture, a secondary site of active growth in the young rabbit (14).

The maxillae form the main portion of the upper jaw. Each maxilla consists of a central portion the body and of five processes—alveolar, palatine, orbital, zygomatic, and sphenoorbital (Fig. 1). The ventral portion of the maxilla with the palatine bone forms the hard palate (Fig. 1 B). This structure is represented chiefly by a bony palatine bridge connecting the two sides of the skull between the premolars and molars. It forms the roof of the oral cavity and a portion of the floor of the nasal cavity. Immediately in front of it the palatine surface is perforated by a pair of large incisive foramina, which are broadly open to the nasal fossae (Fig. 1 B). Laterally, where the palatine bones articulate with the palatine processes of the maxillae are the palatine foramina.

The premaxilla forms the anterior part of the upper jaw. It comprises a central portion, the body including the alveolar, frontal and

palatine processes (Fig. 1). The body forms a portion of the palatal surface of the skull and of the lateral boundaries of the incisive foramen. The frontal process of the premaxilla, a somewhat prominent narrow ridge extends posteriorly along the lateral surface of the nasal bone and articulates with the premaxillary process of the frontal bone (Fig. 1 D).

The mandible, the largest element of the facial region, is composed of two portions united anteriorly by the symphysis (Fig. 5). Each half comprises a horizontal portion the body of the mandible, and a posterior vertical portion the ramus. The latter serves for the insertion of the muscles of mastication and for articulation with the skull. The mandibular ramus forms a broad plate the lateral surface of which is occupied by the masseter muscle, while the medial surface serves as an area of insertion for the pterygoid muscles. The surface of the ramus is greatly increased in its posteroventral portion through the expansion of the bone to form the angle. The elongated articular surface is at the end of the condylar process. Just inferior to this on the anterior border of the ramus is the coronoid process. The sigmoid notch is between these two processes. The nerve and vessels of the mandible enter at the mandibular

V Results

A Growing Rabbits

1 Resected septomaxillary region and/or cartilaginous nasal septum (large amounts)

(a) Ante-mortem observations

As early as 4 days after resection of cartilaginous nasal septum there was a reversal of the incisal relationship, with the upper ones being lingual to the lowers. Subsequently the sharp incisal edge on the labial surface was not maintained. Marked overeruption and fractures of the incisors were frequent in the experimental animals with a longer postoperative survival. At times food would become lodged between the spread incisors. These factors sometimes made ingestion difficult. In a few of the experimental animals the weight was less and the fur was not as smooth when compared with the controls.

The face of the experimental rabbit was in marked contrast to the long, smoothly curved, tapered face seen in the operated and unoperated control animals (Fig. 4). The snout became progressively stubby along with the appearance of a pronounced indentation above the tip of the nose. This was suggestive of the face of a bull dog and was prominent less than 3 weeks postoperatively.

(b) Post-mortem observations

Changes noted in the dissected skulls of the experimental animals were limited to the snout in the region anterior to the orbits, zygomas and molars. Although the findings were not always consistent, generally the degree of change varied directly with the amount of septum resected and the postoperative survival period.

The following description is characteristic of the most severe deformities seen in animals with the longest postoperative survival. The snout, when seen from the side, was tapered and shorter than that of the unoperated con-

trol. Whereas the snout in the control animal was the prominent part of the anterior face, this was reversed in the experimental rabbit. There was a marked deflection of the snout in a forward direction beginning anterior to the frontonasal suture. This was in contrast to the smoothly curved dorsum of the control animals (Fig. 5). From below the palate and the incisive foramen were shorter (Fig. 6). From in front, the nasal aperture was smaller. The snout when viewed from above was considerably shorter than that of the litter-mate control animal (Fig. 7).

The nasal bones were markedly shorter and narrower than those of the control animals and converged toward the premaxilla with nasal height and volume markedly reduced. The premaxilla and its frontal process were also shorter. The end of the snout was tapered in the dorsoventral direction.

Examination of the parasagittally sectioned crania revealed in the experimental animals the extent of the septal defect in relation to the remaining septum and deformity of the snout and in the control animals the relation of the extent of the nasal septum to the snout. The site of the beginning of the downward deflection of the nasal bones was correlated with the posterior border of the septal defect which was anterior to the frontonasal suture (Fig. 8 E). Whereas in the control animal the nasal bones and hard palate were approximately parallel, in the experimental animal anterior projections of lines from the surfaces of these bones would soon intersect (Figs 8 F, F). The post-mortem gross findings of the facial skeleton at 18, 35, 55, 91 and 131 days of age are summarized in Table II (Fig. 8).

The left (experimental, No. 14) and right (control, No. 13) sides of the parasagittally sectioned skulls of litter-mate animals with the same survival period were approximated along the posterosuperior and occipital borders

Table 1 Summary of various surgical experiments on the septovomer region in growing and adult rabbits

of age weaned at 6 to 7 weeks of age, killed 16 to 20 weeks later and studied. In addition, in another experiment, where large amounts of cartilaginous nasal septum were resected, the animals were studied at death from 4 to 145 days (11).

In most instances the animals were killed by injecting pentobarbital sodium into the heart. Immediately after death the heads were severed from the body and a portion of the soft tissues was resected. The heads were then fixed in either 70 per cent ethyl alcohol or 10 per cent formalin. Subsequently further dissection was done and the heads were sectioned just to the left of the midline in the parasagittal plane with a small hack saw. The skulls were never boiled since this would destroy the remaining cartilaginous nasal septum.

D Photographs and Roentgenographs

Ante-mortem and post mortem photographs were taken of the heads in the dorsal, lateral, frontal and parasagittal views. Although every effort was made to obtain comparable photographs, this was not always possible.

Lateral roentgenographs were taken of the sectioned skulls with a standard roentgen apparatus at a target film distance of 100 cm operated at 50 and 100 mA, 58-68 kV and an exposure time of $\frac{1}{2}$ to $\frac{3}{4}$ of a second. Previous to this in some instances a barium sulfate paste thick enough to adhere to the margin of the surgical defect in the septum, was applied to outline the septal defect. Tracings were made of selected roentgenographs.

V Results

A. Growing Rabbits

1 Resected septonasal region and/or cartilaginous nasal septum (large amounts)

(a) *Ante-mortem observations*

As early as 4 days after resection of cartilaginous nasal septum there was a reversal of the incisal relationship, with the upper ones being lingual to the lowers. Subsequently the sharp incisal edge on the labial surface was not maintained. Marked overeruption and fractures of the incisors were frequent in the experimental animals with a longer postoperative survival. At times food would become lodged between the spread incisors. These factors sometimes made ingestion difficult. In a few of the experimental animals the weight was less and the fur was not as smooth when compared with the controls.

The face of the experimental rabbit was in marked contrast to the long, smoothly curved, tapered face seen in the operated and unoperated control animals (Fig. 4). The snout became progressively stubby along with the appearance of a pronounced indentation above the tip of the nose. This was suggestive of the face of a bull dog and was prominent less than 3 weeks postoperatively.

(b) *Post-mortem observations*

Changes noted in the dissected skulls of the experimental animals were limited to the snout in the region anterior to the orbits, zygomas and molars. Although the findings were not always consistent, generally the degree of change varied directly with the amount of septum resected and the postoperative survival period.

The following description is characteristic of the most severe deformities seen in animals with the longest postoperative survival. The snout, when seen from the side, was tapered and shorter than that of the unoperated con-

trol. Whereas the snout in the control animal was the prominent part of the anterior face this was reversed in the experimental rabbit. There was a marked deflection of the snout in a forward direction beginning anterior to the frontonasal suture. This was in contrast to the smoothly curved dorsum of the control animals (Fig. 5). From below the palate and the incisive foramen were shorter (Fig. 6). From in front, the nasal aperture was smaller. The snout when viewed from above was considerably shorter than that of the litter mate control animal (Fig. 7).

The nasal bones were markedly shorter and narrower than those of the control animals and converged toward the premaxilla with nasal height and volume markedly reduced. The premaxilla and its frontal process were also shorter. The end of the snout was tapered in the dorsoventral direction.

Examination of the parasagittally sectioned crania revealed in the experimental animals the extent of the septal defect in relation to the remaining septum and deformity of the snout and in the control animals, the relation of the extent of the nasal septum to the snout. The site of the beginning of the downward deflection of the nasal bones was correlated with the posterior border of the septal defect which was anterior to the frontonasal suture (Fig. 8 E). Whereas in the control animal the nasal bones and hard palate were approximately parallel, in the experimental animal anterior projections of lines from the surfaces of these bones would soon intersect (Figs. 8 E F). The post mortem gross findings of the facial skeleton at 18 35 55 91 and 131 days of age are summarized in Table II (Fig. 8).

The left (experimental, No. 14) and right (control, No. 13) sides of the parasagittally sectioned skulls of litter mate animals with the same survival period were approximated along the posterosuperior and occipital borders

Ante mortem and post mortem photographs were taken of the heads in the dorsal, lateral, frontal and parasagittal views. Although every effort was made to obtain comparable photographs, this was not always possible.

Lateral roentgenographs were taken of the sectioned skulls with a standard roentgen apparatus at a target film distance of 100 cm operated at 50 and 100 mA, 58-68 kV and an exposure time of $\frac{1}{8}$ to $\frac{1}{4}$ of a second. Previous to this in some instances a barium sulfate paste thick enough to adhere to the margin of the surgical defect in the septum was applied to outline the septal defect. Tracings were made of selected roentgenographs.

Fig. 4 Post-mortem photographs of lateral view (A) of unoperated control rabbit No. 23 and lateral (B) and frontal views (C) of operated litter-male rabbit No. 21. A portion of the septum and vomer were removed at 28 days of age. Postoperative survival was 118 days. Both animals were killed at 146 days of age. In (B) note the shorter snout, upper jaw and face, acute angulation, and peaking at the region of the fronto-nasal suture, FN and sharp downward direction of nasal bones, N. Contrast this with the longer snout and smoothly curved dorsum of unoperated rabbit in (A). Also note malalignment and over growth of all incisors in (B) and (C). (From Wexler M. R., and Sarraf, B. G. *Arch. Otolaryng.* 305-313 1961)

(Fig. 9) This demonstrated the extreme differences in the size of the snouts

The upper incisors were usually in lingual occlusion with the lower incisors, the reverse of the normal. The upper and lower incisors were overerupted in marked malposition, fractured and deviated. The sharp labial bevel was frequently absent or reversed. The post mortem gross dental findings at 18, 35, 55, 91 and 131 days of age are summarized in Table III (Fig. 8)

(c) Roentgenographic observations

Examination of the roentgenographs of the parasagittally sectioned skulls revealed findings not seen on the gross specimens. Differences between the control (Fig. 10) and experimental (Fig. 11) animals were demonstrated in the lateral roentgenographs of the parasagittally sectioned skulls. Comparisons were significant not only between the two groups but also within each group with increase in the post operative survival period. The post mortem roentgenographic (and gross) facial and dental findings in the control animals and those rabbits which had cartilaginous nasal septum resected are summarized in Tables II and III.

In the experimental animals the anterior dorsum of the skull was flat in the younger animals. With increase in postoperative survival this region was relatively shorter, more posterior and closer dorsoventrally to the upper incisors than in the control rabbits (Fig. 11). Other findings in the experimental animals were larger pulpal cavities in the incisors, an increase in the proportion and amount of

Fig. 4. Ante-mortem lateral, frontal and dorsal (retouched) view photographs of rabbit No. 4 in which a minor amount of the nasal septum was removed and of rabbit No. 18 in which a major amount of the nasal septum was removed at 1 day of age. Note the marked contrast in facial appearance. Animal No. 4 has a relatively normal, long, tapered face whereas animal No. 18 has a short, stubby face with an indentation above the nostrils (lateral view) and an overerupted lower incisor. (From Sarnat, B. G. and Wexler, M. R., *Am. J. Anat.*, 118: 755-767, 1966.)

erupted to unerupted incisor and lesser amounts of alveolar bone supporting the incisors (Figs 10 and 11)

Tracings of the roentgenographs and super positioning of these tracings further illustrated the differences (Fig. 12) The barium sulfate outlined surgical defect in the septum showed the relation to the surrounding area (Fig. 13) In the parasagittal view the basal end of the

upper incisor was in close proximity to where a portion of the septum was resected

2. Resected linear segments of cartilaginous nasal septum

Ante-mortem a lack of forward growth of the upper face, sometimes associated with over eruption and malocclusion of the incisors, was

Fig. 7 Post-mortem dorsal view photographs of skulls of litter-mate rabbits No. 13 (operated control) and No. 14 (resected nasal septum) with postoperative survival of 110 days. In No. 14 note the marked lack of development of the snout. In the right-hand photograph, the right side of the skull of control rabbit No. 13 and the left side of the skull of experimental

rabbit No. 14 were approximated along the postero-dorsal and occipital borders. Note that the differences are limited essentially to the snout area (see Figs. 9 and 12). *IL*, lower incisor. White outlines anterior part of snout. (From Sarraf, B. G. and Wexler M. R., *Am. J. Anat.*, 112: 755-767 1966.)

noted within 6 weeks in some of the experimental animals. In one of the operated on control animals there was overeruption and malocclusion of the incisors but growth of the snout grossly did not appear to be affected. The findings in this group of experimental animals, although less extreme, were related to the findings in the animals with more extensive resection of cartilaginous nasal septum.

Post-mortem, in some animals, no or little septal defect was noted on cursory examination. Upon further study however and after the overlapping margins of the septum were retracted, the true extent of the septal defect could be evaluated (Fig. 14). The segment of cartilage resected was approximately 5×9 mm.

At the time of death the size of the defect

was approximately 3×16 mm. Note the relationship of the direction of the defect to the nasal bone and hard palate (Fig. 14 C).

3. Dislocated cartilaginous nasal septum

External gross examination of the snout, upper and lower jaws, and teeth disclosed no significant gross differences between the operated and unoperated animals. Examination of the transversely sectioned snouts revealed that the dislocated septal cartilage returned to its normal position or close to it so that continuity from the floor of the snout to the dorsum was re-established (Fig. 15). Lateral deviation and deformity of the septum and vomer were noted.

Fig 6 Post-mortem photographs of ventral (upper) and frontodorsal (lower) views of (A) unoperated control rabbit No 23 and (B) operated on litter-mate No. 21 In (B), note that the snout is shorter and broader IF incisive foramen is shorter in (B) N nasal bone Note again malalignment and overgrowth of incisors. B Adult Rabbits

Resected cartilaginous nasal septum (large amounts)

Ante-mortem observations of the snout and incisors revealed no gross differences between

the control and experimental rabbits. In a few of the latter group a clear nasal discharge was noted at times. Post mortem gross examination of the lateral and parasagittal views of the face jaws, and incisors likewise showed no gross differences between the control and experimen-

Fig 8 Post-mortem photographs, arranged according to postoperative survival, of parasagittally sectioned skulls of rabbits which had cartilaginous nasal septum resected at 14 or 21 days of age with a post operative survival of 4 to 110 days. Note the flatness of the anterior dorsum in (A), (B) and (C) with some deflection in (D) and more marked deflection in (E). Also note in (A) that the upper incisal edge is just lingual to the lower one. With the increase in postoperative survival (B, C, D and E) the discrepancy becomes greater as does the overeruption of the incisors. When the clinical crown of the incisor becomes quite long, it may fracture (F), operated control rabbit which had the preliminary

surgical procedure but no cartilaginous nasal septum resected. Note the length of the snout, the smoothly curved dorsum, the length and position of the nasal bone, the extent of the intact cartilaginous nasal septum and the form, position and relationship of the incisors in contrast to experimented on litter-mate (E). The nasal bones converge in an anterior direction toward the palate in the animals with severe deformity (E) whereas in the operated control animals the nasal bones tend to remain parallel (F) as indicated by the black dashes. A septal defect FN frontonasal suture S septum See Figs. 10 and 11 (From Sarnat, B. G. and Wexler M. R. *Brit. J. Plast. Surg.* 22 313-323 1969)

From Samat, B. H. and Wender, M. R., *Brit. J. Plast. Surg.* 22, 313-323, 1969.

The response to resection of cartilaginous nasal septum varied with the age of the rabbit, the amount (and site) resected as well as the duration of the postoperative survival. Although an attempt was made to standardize the surgical procedure the same amount of cartilaginous nasal septum was not resected from comparable sites in all animals. The degree of change varied from relatively little to marked, depending on these factors. Severe deformities involving many lateral facial structures were produced by removing portions of this midline structure, the cartilage of the nasal septum.

In a few animals which expired at the time of, or shortly after surgery post-mortem examination revealed that approximately 60 to 75 per cent of the cartilaginous portion of the

septum was removed. In animals with a 4 month postoperative survival, the surgical defect represented approximately only 30 to 40 per cent of the septum. The defect may have remained nearly the same in actual size but proportionately it became smaller with continued growth of the cartilaginous nasal septum. Histologic investigation of the septal border may provide information regarding the regenerative activity at this site.

Questions arose as to the role of the cartilaginous nasal septum and its sites of activity in relation to growth and form of the snout. Is the snout deformity a result of lack of growth of the cartilaginous nasal septum or lack of support? In one experiment, central horizontal segments, 3-6 mm wide and 9-15 mm long, of cartilaginous nasal septum

Fig 9 Post-mortem lateral view photographs of left parasagittally sectioned skulls of littermate rabbits No 13 (operated control) right side and No. 14 (resected nasal septum) left side approximated along the posterodorsal and occipital borders for contrast with a postoperative survival of 110 days (see Figs. 7 and 12) In rabbit No. 13 note the length of the snout and the smoothly curved dorsum. In rabbit

No. 14 note the markedly underdeveloped snout, the downward angulation of the nasal bone in an anterior direction and the smaller nasal aperture. White line denotes anterior part of skull of experimental rabbit No 14 Note that in an anterior direction the nasal bone converges toward the palate See Fig. 12 (From Sarnat, B G and Wexler M R. *Am. J Anat* 118 755 767 1966)

tal rabbits (Fig 16) Inspection of the right half of the left parasagittally sectioned skulls disclosed a large defect of the cartilaginous

nasal septum in the experimental animals (fig. 16 B) No unusual deflection of the nasal bones was noted.

VI Discussion

A The Face and Jaws after Surgical Experimentation with the Septovomer Region

Young rabbits were used to impose injury during a period of rapid growth It was demonstrated that resection of the septovomer region in growing rabbits elicited a prompt and early response manifested by a deceleration of growth of adjacent bones A similar response was obtained, moreover when large amounts of only cartilaginous nasal septum were resected with particular care taken not to injure the septovomer joint The severity of

the growth arrest became strikingly apparent with a longer postoperative survival

Ante-mortem the snout of the unaffected animal was long and tapered with a smoothly curved dorsum (Fig. 4 No 4) This was in contrast to the snout of the affected animal which was short, stubby rounded with a sharp deflection of the dorsum in an anterior direction and an indentation above the nostrils (Fig 4 No 18) Post-mortem the dissected skull of the control animal had an appearance comparable with ante-mortem This was not as true with the experimental animal because the soft tissue masked the findings

sociated trauma to the vomer and the septovomer joint in growing rabbits failed to produce any significant gross changes in the external shape and size of the snout, jaws, or teeth. The dislocated septal cartilage returned to its normal position, or close to it, re-

establishing the continuity from the floor of the snout to the dorsum. There were varying degrees of septal and septovomer deformity (Fig. 15). The effects of permanent dislocation without vomeral contact were not determined.

These experiments suggest that the deform-

Fig 12 Approximate tracings (original by Dr Herbert Muchnic) of lateral roentgenographs of right side of parasagittally sectioned skulls of litter-mate rabbits killed at 131 days of age. In control animal No. 13 note the general size, shape, and regularity of the face, jaws and incisors. In experimental animal No. 14 the nasal cartilaginous septum was resected at 21 days of age. Note the smaller size, the different shape, the irregularity of the upper face and a smaller orbit. In the lowermost illustration, the tracings were superimposed along the posterodorsal and occipital borders to contrast the differences between the control and experimental animals. See Figs. 9, 10 E and 11 E (From Sarnat, B. G. and Wexler M. R., *Am. J. Anat.*, 118: 755-767, 1966.)

were resected in growing rabbits (8). After a postoperative survival of 16 weeks a deformity of the snout was noted but it was less than in animals in which larger amounts of cartilaginous nasal septum were resected. At post mortem, an overlap of septal borders was noted at the operative site (Fig. 14 C). These findings were interpreted as a dissipation of the growth force of the cartilaginous nasal

septum at the site of resection with a resulting lack of forward and dorsal growth of the snout.

In a different experiment large amounts of cartilaginous nasal septum were resected in adult rabbits (9). After a postoperative survival of 16 weeks, study of the dissected skulls showed a large septal defect but no deformity of the snout (Fig. 16 B).

Deliberate dislocation of the septum with as-

Fig 16 Post-mortem photographs of right halves of left parasagittally sectioned rabbit skulls. (A), operated control animal No. 13. No cartilaginous nasal septum was resected. (B) cartilaginous nasal septum was resected in this experimental animal N M-1 when it was an adult. Compare with (A) and note similarities of size, shape and regularity of incisors. Also note regularity of dorsal curvature unimpaired by underlying septal defect. (C) cartilaginous nasal septum was resected in this experimental animal No. 11 at 3 weeks of age and killed at approximately 4 months of age. Note growth arrest of snout and malocclusion of incisors. Also note deflection of snout in an anterior direction beginning in the region of septal defect. (From Sarnat, B. G. and Wexler M. R. Arch. Otolaryng., 86, 463-466, 1967.)

large amounts of cartilaginous nasal septum were resected (6, 9). Consequently it was concluded that the malocclusion was related to failure in anterior growth of the snout and not to trauma to the growing tooth at the time of the original surgery. Malocclusion may occur on an inherited basis (19). Injury to growing rodent incisors may lead not only to overcrup-

tion but also disturbances in enamel formation (20). The latter was not found in this experiment.

Along with these face, jaw and dental abnormalities it is possible that there were other anatomic and physiologic alterations of the nose, temporomandibular joints and the rest of the masticatory and respiratory systems.

Fig. 15 Post-mortem photographs of transverse sections of rabbit snouts at the level of the basal end of the incisors of rabbit No. 36 an unoperated control and rabbits No. 27 and No. 29 in which the septum was dislocated laterally. Note the lateral

deviation of the septum in No. 7 and the more marked deformity of the septum and vomer in No. 29. No external deformity of the snout was noted. (From Wexler M. R., and Sarnat, B. G. *Arch. Otolaryng.*, 81: 68-71, 1965.)

ity of the snout after resection of cartilaginous nasal septum in growing rabbits is the result of a lack of growth rather than a lack of support of the cartilaginous nasal septum. Another possible cause of deformity is that of scar tissue resulting from the surgical procedure. On the basis of the above evidence this is not considered to be a factor.

Increase of the cartilaginous nasal septum in height, length and thickness is by both interstitial and perichondrial growth. The relative contributions of each is not known. A study of the proliferative activity of chondrocytes with initiated thymidine indicated the highest activity to be in the anteroinferior and posterior parts of the cartilaginous nasal septum (18A). Although the central zone of the cartilaginous nasal septum had a relatively low rate of proliferation, this rate would result in doubling of the cell population in about 4 weeks. Assuming that a significant increase in septal mass accompanies increased chondrocyte numbers then deformities of the snout might well be anticipated as a consequence of surgical ablation of the central zone early in life.

B Dental Changes

Concomitant with lessened growth of the snout a relative mandibular prognathism resulted with lack of occlusion of the upper and lower incisors. The incisors overerupted in bizarre forms as a result of continuous growth and eruption coupled with a decreased rate of attrition. The relation of the upper incisors lingual to the lower ones and overeruption of the incisors proved to be early clinical signs of a developing deformity of the snout. This was noted as early as 4 days postoperatively. In other experimental rabbits where snout length was not as severely affected, occlusion was relatively normal.

Another possible cause for this deformity is that the basal ends of the incisors, adjacent but lateral to the septovomer region were traumatized at the time of surgery. No dental deformities were noted (i) in the operated control animals in which the surgical procedure was carried out up to removal of cartilaginous nasal septum (ii) in rabbits in which the cartilaginous nasal septum was dislocated but not resected (6) or (iii) in adult rabbits in which

movement of the face (1, 2, 4, 27-32). Although each of these regions exemplifies endochondral bone growth, the histologic arrangement of the adjacent tissues differs (31). These differences account for some of the variations in growth of different bones (33).

Surgical removal of the sphenooptic synchondrosis growth center in rats produced a shorter skull (34). The changes in form were limited mostly to the posterior half of the neurocranium, both base and vault. None was noted in the face—jaws or teeth.

2. Secondary growth sites

Growth of bones is also active at secondary or accommodating growth sites (4, 22, 35). Appositional growth, as well as modeling resorption, occurs on the surfaces of bones (periosteal and endosteal) and contributes to growth and movement in all directions. Sutural growth is found only in the skull. Growth of the cartilaginous nasal septum influences sutural growth and contributes to downward and forward growth of the face and palate (28). The contents of certain other cavities of the skull likewise influence the growth of a complex of adjoining bones and sutures. Examples are the brain and the neurocranium, the orbital contents and orbit, the tongue and the oral cavity. Muscle activity local and regional, also plays an important role.

In growing rabbits, considerable growth of bones occurred at the frontonasal suture (14). The nasal side contributed approximately twice the amount that the frontal side contributed. Extirpation of this suture however did not affect grossly growth of the snout (15). Similarly in growing monkeys extirpation of the midpalatine and transpalatine sutures resulted in no gross alterations in either facial or jaw growth (36).

Subsequent to resection of the cartilaginous nasal septum, the nasal bones were found to be shorter than those of the control animals. With less impetus from growth of the cartilaginous nasal septum no doubt secondary

activity at the frontonasal suture was reduced. This change in activity at the frontonasal suture could be studied by means of radiopaque implants and serial roentgenographs.

D Clinical Considerations

Findings in experimental animals may be of assistance in understanding normal and abnormal growth of bones in the human being. Deformities of the nasal septum and associated structures seen clinically in the adult have been considered manifestations of severe nasal injury incurred during an earlier period. Since the above experimental findings confirm this thesis, it would be advisable that young children, who have sustained injuries to the cartilaginous septum and nose, be treated and observed not only for the immediate but also for late deformities. In addition they should be followed for deformities of the teeth, jaws and face.

In a child with a complete bilateral cleft palate, the upper face may be unable to obtain a full expression of downward and forward growth because of lack of contact of the palatal shelves with the ventral-free actively growing septovomer region (Fig. 17). Furthermore, trauma to the septal region, during cleft palate or septal surgery might have an untoward effect upon growth of the nose and upper jaw and face. Injury to the midpalatine or transpalatine sutures which are secondary growth sites, is of less import (36).

In surgical procedures related to the nasal bones and septum in the actively growing child one would not anticipate a growth arrest in relation to trauma to the nasal bones. Some deficiency of growth might result, however if there were sufficient trauma to the cartilaginous nasal septum. This statement in regard to differential reaction is based upon the absence of gross deformity of the snout in rabbits after either extirpation of the frontonasal suture or temporary dislocation of the nasal septum but the presence of deformity of the snout after resection of cartilaginous nasal septum (37).

C Growth of Bones

The dynamics of the growth of bones are complicated (1). The basic pattern of a bone is inherent. The form and architecture may be modified however during prenatal and postnatal growth by local regional and systemic influences acting through the internal and external environments. The end result, at any given time, is a record of the effects of all the vicissitudes.

A great deal has been learned about the prenatal and postnatal etiology of facial and other abnormalities in the experimental animal. The material of this report is only part of a series of experiments in which the relationship of injury to postnatal growth has been studied (1, 2, 21, 22). Throughout our lives we are constantly reacting to our environment. Variations in temperature, light, humidity, atmospheric pressure, terrestrial and extraterrestrial radiation, and gravity affect us. In addition, the vast number of toxic agents, intentionally or unintentionally ingested in our food (or essential deficiencies) and water and inhaled in our air determine our destinies. Consider the effect of our environment upon the skeletal growth sites and the resulting changes in size and shape of the jaws, face, and body.

There are many mechanisms (nervous, hormonal, metabolic, enzymatic) by which the environment directly induces adaptive changes (23). Environmental stresses can interact either directly such as variations in temperature and oxygen, or indirectly with the genetically controlled enzyme-forming system. There is no evidence that environmental stresses can induce genetic change. Rather, the stress permits such genetic changes as may occur in natural mutations to be realized and fixed.

Young rats exposed to cold stress had a smaller skull, a longer face in relation to the cranial vault, a narrower nose, a rounder neurocranium, and a shorter femur (24). Natives living at high altitudes and exposed to the environmental stresses of hypoxia and cold

have a slower postnatal growth and lesser adolescent growth spurt than other groups (25). On earth, gravity is considered normal or 1.0 g. What skeletal and other changes will occur in environments of hypogravity (moon 0.18 g) or hypergravity (Jupiter 2.65 g)? These and other factors are of great interest to the new field of cosmic biology and should be of concern to us as surgeons.

A basic physiologic concept is that throughout life, bone is in a continuous state of apposition and resorption along periodical and endosteal surfaces. Consequently, skeletal size and shape are always subject to change. When the skeletal mass increases, as in children, apposition is more active than resorption. Endochondral and sutural growth are active. When the skeletal mass is constant, as in the adult, apposition and resorption, although active, are in equilibrium. Endochondral and sutural growth have ceased. When the skeletal mass decreases, as in old age, resorption is more active than apposition.

Of the three modes of postnatal growth of bones, endochondral may be considered to be primary. The other two, appositional (and resorptive) and sutural, may be considered to be secondary. The skull has proved to be a rich source of study since nowhere else in the body are representatives of all of these different sites found. As a result of the activities of these sites, the facial skeleton increases in size in all three planes—height, width, and length. But it grows in these three dimensions differentially at different times and at different rates (14, 26, 27, 28).

1 Primary growth centers

Primary endochondral centers of growth are epiphyses in the long or tubular bones, the costochondral junction of ribs and the clavicle. Some of those in the skull are the sphenoethmoidal and sphenoccipital synchondroses, the septoethmoidal and septopresphenoid joints, and mandibular condyle. These centers contribute to the downward and forward growth and

movement of the face (1, 2, 4, 27-32). Although each of these regions exemplifies endochondral bone growth, the histologic arrangement of the adjacent tissues differs (31). These differences account for some of the variations in growth of different bones (33).

Surgical removal of the sphenoccipital synchondrosis growth center in rats produced a shorter skull (34). The changes in form were limited mostly to the posterior half of the neurocranium, both base and vault. None was noted in the face, jaws or teeth.

2. Secondary growth sites

Growth of bones is also active at secondary or accommodating growth sites (4, 22, 35). Appositional growth, as well as modeling resorption, occurs on the surfaces of bones (periosteal and endosteal) and contributes to growth and movement in all directions. Sutural growth is found only in the skull. Growth of the cartilaginous nasal septum influences sutural growth and contributes to downward and forward growth of the face and palate (28). The contents of certain other cavities of the skull likewise influence the growth of a complex of adjoining bones and sutures. Examples are the brain and the neurocranium, the orbital contents and orbit, the tongue and the oral cavity. Muscle activity local and regional, also plays an important role.

In growing rabbits, considerable growth of bones occurred at the frontonasal suture (14). The nasal side contributed approximately twice the amount that the frontal side contributed. Extirpation of this suture however did not affect grossly growth of the snout (15). Similarly in growing monkeys extirpation of the midpalatine and transpalatine sutures resulted in no gross alterations in either facial or jaw growth (36).

Subsequent to resection of the cartilaginous nasal septum, the nasal bones were found to be shorter than those of the control animals. With less impetus from growth of the cartilaginous nasal septum no doubt secondary

activity at the frontonasal suture was reduced. This change in activity at the frontonasal suture could be studied by means of radiopaque implants and serial roentgenographs.

D Clinical Considerations

Findings in experimental animals may be of assistance in understanding normal and abnormal growth of bones in the human being. Deformities of the nasal septum and associated structures seen clinically in the adult have been considered manifestations of severe nasal injury incurred during an earlier period. Since the above experimental findings confirm this thesis, it would be advisable that young children, who have sustained injuries to the cartilaginous septum and nose be treated and observed not only for the immediate but also for late deformities. In addition they should be followed for deformities of the teeth, jaws and face.

In a child with a complete bilateral cleft palate, the upper face may be unable to obtain a full expression of downward and forward growth because of lack of contact of the palatal shelves with the ventral-free actively growing septovomer region (Fig. 17). Furthermore, trauma to the septal region, during cleft palate or septal surgery might have an untoward effect upon growth of the nose and upper jaw and face. Injury to the midpalatine or transpalatine sutures which are secondary growth sites, is of less import (36).

In surgical procedures related to the nasal bones and septum in the actively growing child one would not anticipate a growth arrest in relation to trauma to the nasal bones. Some deficiency of growth might result, however if there were sufficient trauma to the cartilaginous nasal septum. This statement in regard to differential reaction is based upon the absence of gross deformity of the snout in rabbits after either extirpation of the frontonasal suture or temporary dislocation of the nasal septum but the presence of deformity of the snout after resection of cartilaginous nasal septum (37).

C Growth of Bones

The dynamics of the growth of bones are complicated (1). The basic pattern of a bone is inherent. The form and architecture may be modified however during prenatal and postnatal growth by local, regional and systemic influences acting through the internal and external environments. The end result, at any given time, is a record of the effects of all the vicissitudes.

A great deal has been learned about the prenatal and postnatal etiology of facial and other abnormalities in the experimental animal. The material of this report is only part of a series of experiments in which the relationship of injury to postnatal growth has been studied (1, 2, 21, 22). Throughout our lives we are constantly reacting to our environment. Variations in temperature, light, humidity, atmospheric pressure, terrestrial and extraterrestrial radiation and gravity affect us. In addition the vast number of toxic agents, intentionally or unintentionally ingested in our food (or essential deficiencies) and water and inhaled in our air determine our destinies. Consider the effect of our environment upon the skeletal growth sites and the resulting changes in size and shape of the jaws, face, and body.

There are many mechanisms (nervous, hormonal, metabolic, enzymatic) by which the environment directly induces adaptive changes (23). Environmental stresses can interact either directly such as variations in temperature and oxygen, or indirectly with the genetically controlled enzyme-forming system. There is no evidence that environmental stresses can induce genetic change. Rather the stress permits such genetic changes as may occur in natural mutations to be realized and fixed.

Young rats exposed to cold stress had a smaller skull, a longer face in relation to the cranial vault, a narrower nose, a rounder neurocranium and a shorter femur (24). Natives living at high altitudes and exposed to the environmental stresses of hypoxia and cold

have a slower postnatal growth and lesser adolescent growth spurt than other groups (25). On earth, gravity is considered normal or 1.0 g. What skeletal and other changes will occur in environments of hypogravity (moon, 0.18 g) or hypergravity (Jupiter, 2.65 g)? These and other factors are of great interest to the new field of cosmic biology and should be of concern to us as surgeons.

A basic physiologic concept is that throughout life bone is in a continuous state of apposition and resorption along periosteal and endosteal surfaces. Consequently skeletal size and shape are always subject to change. When the skeletal mass increases, as in children, apposition is more active than resorption. Endochondral and sutural growth are active. When the skeletal mass is constant, as in the adult, apposition and resorption although active, are in equilibrium. Endochondral and sutural growth have ceased. When the skeletal mass decreases, as in old age, resorption is more active than apposition.

Of the three modes of postnatal growth of bones, endochondral may be considered to be primary. The other two appositional (and resorptive) and sutural may be considered to be secondary. The skull has proved to be a rich source of study since nowhere else in the body are representatives of all of these different sites found. As a result of the activities of these sites the facial skeleton increases in size in all three planes—height, width and length. But it grows in these three dimensions differentially at different times and at different rates (14, 26, 27, 28).

1 Primary growth centers

Primary endochondral centers of growth are epiphyses in the long or tubular bones, the costochondral junction of ribs and the clavicle. Some of those in the skull are the sphenoethmoidal and sphenoccipital synchondroses, the septoethmoidal and septopresphenoid joints, and mandibular condyle. These centers contribute to the downward and forward growth and

movement of the face (1, 2, 4, 27-32). Although each of these regions exemplifies endochondral bone growth, the histologic arrangement of the adjacent tissues differs (31). These differences account for some of the variations in growth of different bones (33).

Surgical removal of the sphenooccipital synchondrosis growth center in rats produced a shorter skull (34). The changes in form were limited mostly to the posterior half of the neurocranium, both base and vault. None was noted in the face, jaws or teeth.

2. Secondary growth sites

Growth of bones is also active at secondary or accommodating growth sites (4, 22, 35). Appositional growth, as well as modelling resorption, occurs on the surfaces of bones (periosteal and endosteal) and contributes to growth and movement in all directions. Sutural growth is found only in the skull. Growth of the cartilaginous nasal septum influences sutural growth and contributes to downward and forward growth of the face and palate (28). The contents of certain other cavities of the skull likewise influence the growth of a complex of adjoining bones and sutures. Examples are the brain and the neurocranium, the orbital contents and orbit, the tongue and the oral cavity. Muscle activity local and regional, also plays an important role.

In growing rabbits, considerable growth of bones occurred at the frontonasal suture (14). The nasal side contributed approximately twice the amount that the frontal side contributed. Extirpation of this suture however did not affect grossly growth of the snout (15). Similarly in growing monkeys extirpation of the midpalatine and transpalatine sutures resulted in no gross alterations in either facial or jaw growth (36).

Subsequent to resection of the cartilaginous nasal septum, the nasal bones were found to be shorter than those of the control animals. With less impetus from growth of the cartilaginous nasal septum no doubt secondary

activity at the frontonasal suture was reduced. This change in activity at the frontonasal suture could be studied by means of radiopaque implants and serial roentgenographs.

D Clinical Considerations

Findings in experimental animals may be of assistance in understanding normal and abnormal growth of bones in the human being. Deformities of the nasal septum and associated structures seen clinically in the adult have been considered manifestations of severe nasal injury incurred during an earlier period. Since the above experimental findings confirm this thesis, it would be advisable that young children, who have sustained injuries to the cartilaginous septum and nose, be treated and observed not only for the immediate but also for late deformities. In addition they should be followed for deformities of the teeth, jaws and face.

In a child with a complete bilateral cleft palate, the upper face may be unable to obtain a full expression of downward and forward growth because of lack of contact of the palatal shelves with the ventral-free actively growing septovomer region (Fig. 17). Furthermore, trauma to the septal region, during cleft palate or septal surgery might have an untoward effect upon growth of the nose and upper jaw and face. Injury to the midpalatine or transpalatine sutures which are secondary growth sites, is of less import (36).

In surgical procedures related to the nasal bones and septum in the actively growing child one would not anticipate a growth arrest in relation to trauma to the nasal bones. Some deficiency of growth might result, however if there were sufficient trauma to the cartilaginous nasal septum. This statement in regard to differential reaction is based upon the absence of gross deformity of the snout in rabbits after either extirpation of the frontonasal suture or temporary dislocation of the nasal septum but the presence of deformity of the snout after resection of cartilaginous nasal septum (37).

C Growth of Bones

The dynamics of the growth of bones are complicated (1) The basic pattern of a bone is inherent. The form and architecture may be modified however during prenatal and postnatal growth by local, regional and systemic influences acting through the internal and external environments. The end result, at any given time is a record of the effects of all the vicissitudes

A great deal has been learned about the prenatal and postnatal etiology of facial and other abnormalities in the experimental animal. The material of this report is only part of a series of experiments in which the relationship of injury to postnatal growth has been studied (1 2 21 22) Throughout our lives we are constantly reacting to our environment. Variations in temperature, light, humidity, atmospheric pressure, terrestrial and extraterrestrial radiation and gravity affect us. In addition the vast number of toxic agents intentionally or unintentionally ingested in our food (or essential deficiencies) and water and inhaled in our air determine our destinies. Consider the effect of our environment upon the skeletal growth sites and the resulting changes in size and shape of the jaws, face, and body.

There are many mechanisms (nervous, hormonal, metabolic, enzymatic) by which the environment directly induces adaptive changes (23) Environmental stresses can interact either directly such as variations in temperature and oxygen, or indirectly with the genetically controlled enzyme forming system. There is no evidence that environmental stresses can induce genetic change. Rather the stress permits such genetic changes as may occur in natural mutations to be realized and fixed.

Young rats exposed to cold stress had a smaller skull, a longer face in relation to the cranial vault, a narrower nose, a rounder neurocranium and a shorter femur (24) Natives living at high altitudes and exposed to the environmental stresses of hypoxia and cold

have a slower postnatal growth and lesser adolescent growth spurt than other groups (25) On earth gravity is considered normal or 1.0 g. What skeletal and other changes will occur in environments of hypogravity (moon 0.18 g) or hypergravity (Jupiter 2.65 g)? These and other factors are of great interest to the new field of cosmic biology and should be of concern to us as surgeons.

A basic physiologic concept is that throughout life bone is in a continuous state of apposition and resorption along periosteal and endosteal surfaces. Consequently skeletal size and shape are always subject to change. When the skeletal mass increases, as in children, apposition is more active than resorption. Endochondral and sutural growth are active. When the skeletal mass is constant as in the adult, apposition and resorption although active, are in equilibrium. Endochondral and sutural growth have ceased. When the skeletal mass decreases, as in old age, resorption is more active than apposition.

Of the three modes of postnatal growth of bones, endochondral may be considered to be primary. The other two appositional (and resorptive) and sutural may be considered to be secondary. The skull has proved to be a rich source of study since nowhere else in the body are representatives of all of these different sites found. As a result of the activities of these sites the facial skeleton increases in size in all three planes—height, width and length. But it grows in these three dimensions differentially at different times and at different rates (14 26 27 28).

1 Primary growth centers

Primary endochondral centers of growth are epiphyses in the long or tubular bones, the costochondral junction of ribs and the clavicle. Some of those in the skull are the sphenoethmoidal and sphenooccipital synchondroses, the septoethmoidal and septopresphenoid joints, and mandibular condyle. These centers contribute to the downward and forward growth and

that of the orbital contents to the growth of the orbit and the brain to the growth of the neurocranium.

When lesser amounts of cartilaginous nasal septum were resected (linear horizontal segments), the snout and dental deformities were also less pronounced. After temporary lateral dislocation of the cartilaginous nasal septum neither snout nor dental abnormalities were noted. All of the above were done in young rabbits. When large amounts of cartilaginous nasal septum were resected in adult rabbits, neither snout nor dental changes were observed.

The cartilaginous nasal septum is important

in the growth and development of the upper face of the rabbit. This information is applicable to human beings is of particular clinical significance in young patients with injuries to this area or with bilateral complete cleft palates.

Functional and cosmetic treatment of growth deficiencies of the upper face and related areas is a difficult one. The dysplastic pattern of growth continues. Even though the deformity may not be progressive it is not self-correcting and there is no way to compensate for lost or retarded growth. Orthodontic, prosthetic and surgical procedures give functional and cosmetic improvement. The surgical procedures

commonly used are directed toward contributing bulk and altering malposition. Osteotomy with or without a bone graft, and bone cartilage or alloplastic materials as a masking procedure, have been utilized. Certain aspects of treatment may be undertaken when the patient is still growing but the final result can not be attained until growth of the face has ceased.

VII Summary and Conclusions

A series of surgical experiments on the septovomer region of young growing and adult rabbits is reviewed and summarized. The purpose was to relate this information to basic concepts of growth of bones and to possible clinical significance.

After resection of the septovomer region and/or large amounts of only cartilaginous nasal septum in young growing rabbits there was, as early as 4 days postoperatively, a deceleration of growth of the snout, a reversal of the incisal relationship and an overeruption of the incisors. At post mortem in the experimental animals as contrasted with the controls, the snout was shorter and smaller with a resulting severe relative mandibular prognathism.

The nasal and premaxillary bones were smaller as were the nasal cavity and piriform aperture. At the posterior border of the septal defect there was a marked downward deflection of the nasal bones in an anterior direction. This was in contrast to the smoothly curved dorsum of the control animals. The extent and severity of the deformity varied approximately with the amount of cartilaginous nasal septum resected, the age of the animal at the time of resection and the length of the postoperative survival. It is concluded that after resection the remaining cartilaginous nasal septum is unable to attain its full expression of growth. The relationship of the cartilaginous nasal septum to growth of the snout can be compared with

that of the orbital contents to the growth of the orbit and the brain to the growth of the neurocranium.

When lesser amounts of cartilaginous nasal septum were resected (linear horizontal segments), the snout and dental deformities were also less pronounced. After temporary lateral dislocation of the cartilaginous nasal septum neither snout nor dental abnormalities were noted. All of the above were done in young rabbits. When large amounts of cartilaginous nasal septum were resected in adult rabbits, neither snout nor dental changes were observed.

The cartilaginous nasal septum is important

in the growth and development of the upper face of the rabbit. This information if applicable to human beings is of particular clinical significance in young patients with injuries to this area or with bilateral complete cleft palates.

I GENERAL VIEWPOINTS INTRODUCTION

Before the era of chemotherapeutics and antibiotics the main interest of the otologist was focused on the healing processes of the diseased middle ear such as the character of the discharge and symptoms, indicating complications from adjacent structures. The condition of the middle ear was judged after inspection through an ordinary ear speculum or a Siegle's speculum. Modern ear microscopes were not available. For special investigation monocular microscopes had been constructed and used very early. These microscopes, however, had

many drawbacks and were never developed for routine clinical use. As a matter of fact, two Swedish otologists, C. O. Nylén and G. Holmgren were among the initiators of otomicroscopy.

The International O-R. L. Congress in Amsterdam in 1953 was important for the development of modern reconstructive otosurgery because Zöllner and Wallstein presented their reports of pioneer work in this field, which led to increased activity all over the world. This new clinical activity was further based on the availability of chemotherapeutics and antibiotics as well as on modern otomicroscopes and new electro-acoustical hearing tests.

The transmission mechanism is principally characterized by the following factors. From the physical point of view the drum and ossicular chain are acting as a transformer of sound pressure during the collection and conduction of sound. The efficiency of this mechanism is determined by the relation between the acoustically active surface of the drum and the surface of the oval window with an additional lever mechanism of the ossicular chain. This effect has been determined among others by Békésy and for frequencies under 2000 Hz it lies in the 25—30 dB level. In relation to the round window membrane the normal drum has a dampening and phase changing action, the sound protection. Small perforations of the drum, particularly when they are situated in the anterior parts and when the ossicular chain is normal, influence the hearing threshold very little because the sound pressure transformation still is good. When there are perforations in the posterior parts of the drum and when the ossicular chain is not intact, the sound pressure difference between the labyrinth windows is reduced as well as the normal difference in phase between the sound waves reaching the oval window and the round window. Thus a cancellation of the normal sound protection may result in a hearing loss of the same size as the loss of the sound pressure transformer, i.e. 25—30 dB. In cases with subtotal drum perforation and loss of the ossicular chain both labyrinth windows are exposed to the sound waves. Such patients are clinically defined as "window hearers" (Zöllner). According to the above mentioned factors the hearing loss in such cases lies in the 50—60 dB level. In a series of 19 cases of chronic otitis of this type the average hearing loss in the frequencies 250—500—1000 Hz was found to be ca 50 dB (Hjorth, Lundborg & Rösler). When the drum is intact, but the ossicular chain is interrupted in its continuity there is a loss of the sound pressure transformation (25—30 dB) and a reduction of the sound protection, which totally

results in a hearing loss of ca 50—60 dB. When the ossicular chain is fixed in its epitympanic portion ("fixed malleus syndrome" Goodhill) or when the stapedial footplate is fixed in the oval window (otosclerosis, tympanosclerosis) it may result in an audiometrically similar transmission hearing loss.

One has tried to define different types of transmission loss according to estimated changes concerning the mass, stiffness and elasticity of the transmission system, when this is influenced by different types of pathology.

These aims to classify various types of transmission loss from the physical point of view and evaluate the different physical factors, so far do not seem to have had any clinical importance.

PATHOLOGY

The chronic otitis, as is well known, has a complex pathological-anatomical basis, which is characterized by several dimensions. Different phases of the disease can be distinguished a) healed processes 2) latent inflammatory reactions and c) acute recurrences. Individual cases reveal combinations of a), b) and c). From the pathogenetic point of view a) chronic otitis media b) inflammation of the mucous membrane and c) osteitis can be considered.

Middle ear pathology is localized to the drum, the mucous membrane, the ossicles, the ligaments and muscles or the Eustachian tube. The changes of the drum are constituted of changes in consistency forming, for instance, scars and of perforations. The scars appear either atrophic or hypertrophic by formation of new connective tissue, hyalinization, calcification or ossification. When there is a perforation, sometimes epithelium is migrating over its margin on the promontorial wall. The middle ear mucosa can be changed in many ways, for instance hyperplasia, formation of cysts, granulations or epithelial threads between and around the ossicles. When exudative processes are organized or in

The technique of otoscopy had been further developed meanwhile and was also more widely used. Earlier the aim of otoscopy was mainly topographical, i.e. to investigate pathological changes requiring removal by surgery. Now the aim of otoscopy was more to establish a functional diagnosis with the emphasis on conservation to make reconstructive surgery possible.

The Zeiss operation microscope for instance, has a system of prisms diminishing the convergence of the visual axes of the eyes, making stereoscopic observations through the external meatus possible. This microscope also through another elaborate prismatic system illuminates the observed area completely. Thus the meticulous observation of the tiny middle ear structures and also their manipulation with different instruments is greatly facilitated. As a consequence of this development the use of otomicroscopy also was widened, including various diagnostic and therapeutic measures. Without exaggeration it can be stated that modern otosurgery would be impossible without these microscopes. The functional approach in otomicroscopy has led to some direct tests of sound transmission: "the remaining parts of the middle ear were also examined concerning their sound conduction properties (Zöllner)" for instance by the use of prosthesis tests, acoustic probe tests, Gellé-tests, pneumophone test ad modum van Dishoeck, registration of stapedius reflex etc. Each test has a different value in every individual case and therefore the combination of otomicroscopy and functional testing was described as "transmission testing" (Lundborg 1957). This type of transmission testing has to be completed with an evaluation of the tubar function and the cochlear function as well.

Experiences from various institutions during two decades of reconstructive otosurgery are quite different. Therefore the value of reconstructive otosurgery is debated. One reason for that is probably the varying degree of exactness of the preoperative evaluation of each case in

different case materials. Therefore these materials probably also constitute somewhat different conditions concerning the indications for reconstructive middle ear surgery.

The improvement of hearing aids during this period has also made the treatment of deafness easier. In the Scandinavian countries the resources for medical and social rehabilitation of patients with hearing loss have been raised through special audiological units and hearing centers, serving the ENT-clinics. A sociomedical legislation makes it possible to prescribe hearing aids and various accessories to hearing loss patients without costs to them.

Thus the prescription of hearing aids is a further therapeutic possibility where reconstructive otosurgery is not chosen. Different opinions regarding the indications for surgery and also different degrees of surgical activity may influence the choice between the two therapeutic possibilities. In many cases it is necessary to use both methods. Therefore those patient groups, which are referred preliminary either for otosurgical or electroacoustical treatment to a certain extent are identical. This emphasizes the importance of close contact and cooperation between otological and audiological activities.

FUNCTION

During the last decades many details have been clarified concerning the function of both the normal and pathological middle ear. Otosurgical and clinical-audiometrical methods and experiments on animals have been utilized. The sound transmission through the middle ear has been studied on series of experimental animals and also on the temporal bones from cadavers. Different types of drum perforations have been arranged as well as different kinds of obstacles, influencing the mobility of the drum and the ossicular chain. Thus various clinical situations have been imitated and the corresponding hearing loss has been measured.

The transmission mechanism is principally characterized by the following factors. From the physical point of view the drum and ossicular chain are acting as a transformer of sound pressure during the collection and conduction of sound. The efficiency of this mechanism is determined by the relation between the acoustically active surface of the drum and the surface of the oval window with an additional lever mechanism of the ossicular chain. This effect has been determined among others by Békésy and for frequencies under 2000 Hz it lies in the 25—30 dB level. In relation to the round window membrane the normal drum has a dampening and phase changing action, the sound protection. Small perforations of the drum, particularly when they are situated in the anterior parts and when the ossicular chain is normal, influence the hearing threshold very little, because the sound pressure transformation still is good. When there are perforations in the posterior parts of the drum, and when the ossicular chain is not intact, the sound pressure difference between the labyrinth windows is reduced as well as the normal difference in phase between the sound waves reaching the oval window and the round window. Thus a cancellation of the normal sound protection may result in a hearing loss of the same size as the loss of the sound pressure transformer i.e. 25—30 dB. In cases with subtotal drum perforation and loss of the ossicular chain both labyrinth windows are exposed to the sound waves. Such patients are clinically defined as "window hearers" (Zöllner). In a series of 19 cases of chronic otitis of this type the average hearing loss in the frequencies 250—500—1000 Hz was found to be ca 50 dB (Hjorth, Lundborg & Röslér). When the drum is intact, but the ossicular chain is interrupted in its continuity there is a loss of the sound pressure transformation (25—30 dB) and a reduction of the sound protection, which actually

results in a hearing loss of ca 50—60 dB. When the ossicular chain is fixed in its epitympanic portion ("fixed malleus syndrome" Goodhill) or when the stapedial footplate is fixed in the oval window (otosclerosis, tympanosclerosis) it may result in an audiometrically similar transmission hearing loss.

One has tried to define different types of transmission loss according to estimated changes concerning the mass, stiffness and elasticity of the transmission system, when this is influenced by different types of pathology.

These aims to classify various types of transmission loss from the physical point of view and evaluate the different physical factors, so far do not seem to have had any clinical importance.

PATHOLOGY

The chronic otitis, as is well known, has a complex pathological-anatomical basis, which is characterized by several dimensions. Different phases of the disease can be distinguished a) healed processes b) latent inflammatory reactions and c) acute recurrences. Individual cases reveal combinations of a), b) and c). From the pathogenetic point of view a) chronic otitis purulenta b) inflammation of the mucous membrane and c) osteitis can be considered.

Middle ear pathology is localized to the drum, the mucous membrane, the ossicles, the ligaments and muscles or the Eustachian tube. The changes of the drum are constituted of changes in consistency forming, for instance, scars and of perforations. The scars appear either atrophic or hypertrophic by formation of new connective tissue, hyaline, calcification or ossification. When there is a perforation, sometimes epithelium is ingrowing over its margins on the preperforation wall. The middle ear muscles can be changed in many ways, for instance by atrophy. Formation of cysts, granulomas or epithelial strands between and around the ossicles. When reparative processes are organized or in

The technique of otoscopy had been further developed meanwhile and was also more widely used. Earlier the aim of otoscopy was mainly topographical, i.e. to investigate pathological changes requiring removal by surgery. Now the aim of otoscopy was more to establish a functional diagnosis with the emphasis on conservation to make reconstructive surgery possible.

The Zeiss operation microscope, for instance, has a system of prisms diminishing the convergence of the visual axes of the eyes, making stereoscopic observations through the external meatus possible. This microscope also through another elaborate prismatic system illuminates the observed area completely. Thus the meticulous observation of the tiny middle ear structures and also their manipulation with different instruments is greatly facilitated. As a consequence of this development the use of otomicroscopy also was widened, including various diagnostic and therapeutic measures. Without exaggeration it can be stated that modern otosurgery would be impossible without these microscopes. The functional approach in otomicroscopy has led to some direct tests of sound transmission: the remaining parts of the middle ear were also examined concerning their sound conduction properties (Zöllner) for instance by the use of prosthesis tests, acoustic probe tests, Gellé tests, pneumophone test ad modum van Dishoeck, registration of stapedius reflex etc. Each test has a different value in every individual case and therefore the combination of otomicroscopy and functional testing was described as "transmission testing" (Lundborg 1957). This type of transmission testing has to be completed with an evaluation of the tubar function and the cochlear function as well.

Experiences from various institutions during two decades of reconstructive otosurgery are quite different. Therefore the value of reconstructive otosurgery is debated. One reason for that is probably the varying degree of exactness of the preoperative evaluation of each case in

different case materials. Therefore these materials probably also constitute somewhat different conditions concerning the indications for reconstructive middle ear surgery.

The improvement of hearing aids during this period has also made the treatment of deafness easier. In the Scandinavian countries the resources for medical and social rehabilitation of patients with hearing loss have been raised through special audiological units and hearing centers, serving the ENT-clinics. A sociomedical legislation makes it possible to prescribe hearing aids and various accessories to hearing loss patients without costs to them.

Thus the prescription of hearing aids is a further therapeutic possibility where reconstructive otosurgery is not chosen. Different opinions regarding the indications for surgery and also different degrees of surgical activity may influence the choice between the two therapeutic possibilities. In many cases it is necessary to use both methods. Therefore those patient groups, which are referred preliminary either for otosurgical or electroacoustical treatment to a certain extent are identical. This emphasizes the importance of close contact and cooperation between otological and audiological activities.

FUNCTION

During the last decades many details have been clarified concerning the function of both the normal and pathological middle ear. Otosurgical and clinical-audiometrical methods and experiments on animals have been utilized. The sound transmission through the middle ear has been studied on series of experimental animals and also on the temporal bones from cadavers. Different types of drum perforations have been arranged as well as different kinds of obstacles, influencing the mobility of the drum and the ossicular chain. Thus various clinical situations have been imitated and the corresponding hearing loss has been measured.

evaluated and discussed, one can state that, from the clinical point of view it does not seem fruitful to analyze, for instance, the sound pressure transformation, since this is a physical concept. As Kobrak emphasizes, it is almost impossible in diseased ears to assess the different physical factors of the sound conductive system as to their individual role in causing hearing loss. In connection with the otomicroscopic observation it seems more meaningful to state, how different pathology of the middle ear structures seems to influence sound collection and sound conduction which are the clinically comprehensible functions of the middle ear. Another essential component of the transmission mechanism—sound protection—is a well defined and accepted clinical concept.

1. *Chronic otitis with central perforation with anatomically and functionally intact ossicular chain.* Normal middle ear mucosa and functioning Eustachian tube. The hearing loss is depending on the size and position of the perforation from 5–10 dB (small tubar perforations) to 20–30 dB (perforations in the posterior parts of drum, exposing the labyrinth windows). Indirect tympanoscopy with a 3 mm mirror may demonstrate the incudostapedial joint and the processus longus incudis intact and without surrounding inflammatory tissues (granulations, cholesteatoma etc.) See fig. 21—22—23 fig. 25—26, fig. 29—30.

Covering prosthesis may compensate the hearing loss (closed gap in the audiogram), which demonstrates a functioning ossicular chain. Acoustic probe audiograms give via malleus an average transmission 20–25 dB better than via the promontory wall. The pathological changes in such a case influence mainly the sound collection. In such a typical case there is indication for myringoplasty which, as a rule, shall result in a closed gap and intact drum. The results are somewhat varying, depending on technique of operation, type of flap and the possibilities of postopera-

tive, meticulous treatment and control. There are variations of this "typical case" for instance when the epithelium is migrating over the margin of perforation or when the middle ear mucosa shows "allergic reactions" for instance in the form of oedema, hypertrophy adhesives etc. Changes of the tubar function and in the mastoid cell system—according to roentgenograms—of course have to be taken into consideration. Certain of these changes may contradict a myringoplasty.

See Case VII VIII IX

2. *Chronic otitis with central perforation and defective ossicular chain.* The hearing loss depends on the size and position of the perforation (30–60 dB).

Indirect tympanoscopy may show that the distal part of the processus longus incudis is defective, not reaching the stapes. Rather often the distal part of locus is found to be severed by an osteitic process but linked to the caput stapedis with threads of connective tissue. A prosthesis covering the perforation is not then resulting in an improvement of hearing, but if put in contact with the stapes, it may result in a substantial hearing gain. An acoustic probe audiogram gives, as a rule, 20–25 dB better transmission via stapes than via malleus and the promontory wall. The ossicular chain may reveal anatomical continuity but may be rigid at palpation with an ear probe. This results in reduced transmission properties, for instance when there is sclerosis in the artic. malleo-incudis region. (Fixed malleus syndrome, tympanosclerosis etc.) The perforation is reducing the sound collection the changes in the ossicular chain reduce the sound conduction and often also the sound protection is reduced, when the labyrinth windows are exposed.

When the middle ear mucosa appears normal, without signs of cholesteatoma etc. and when the tubar function is normal, the drum perforation may be closed by a tympanoplasty which brings the drum in direct contact with

connection with epithelial lesions, there are sometimes formed new connective tissue eventually with calcification. In certain cases there are also ossification processes, for instance between umbo and the promontory wall resulting in malleus fixation or in the round window niche, resulting in obliteration. In epitympanum such formations may result in hard obliteration of the malleo-incudal articulation and its fixation to the attic wall ("Fixed malleus syndrome"—Goodhill).

Similar formations may also appear in the oval window niche. According to Zöllner and Beck this type of pathology is based on the combination of an epithelial lesion and an allergic reaction resulting in necrosis, lipidization and hyalinization of the connective tissue.

Successively there may easily be a sedimentation of calcium salts. Excessive reactions may result in a hard mass around the stapedial crurae and even ossification of the annular ligament ("Paukensklerose"). In the middle ear there may be a formation of new osteitic tissue—as a surplus formation—resulting from the irritation of the perist during long exudative processes. Thus, part of the ossicular chain may be transformed to masses, which can be difficult to identify. Osteitic processes appear in the ossicular chain during different periods of the chronic otitis, for instance in connection with cholesteatoma but also in connection with direct trauma or pressure by foreign prosthesis materials. Incus is most often affected by these processes. According to Escher ca. 3/5 of the osteitic processes are situated in the distal part of processus longus incudis.

From the pathological-anatomical point of view each case requires an otomicroscopic examination in order to state if there is

a) a central perforation (and to inspect the middle ear mucosa, the continuity of the ossicular chain etc.)

b) a marginal perforation (and thoroughly in

vestigate if this seems to be an epithelized pouch in the attic region with clinical signs to be healed or if there are signs of active reactions with granulations, discharge, cholesteatoma etc.)

c) residuous chronic otitis, for instance with scars or collapsed parts of the drum, adhesive to the promontory wall at some parts, eventually revealing reduced mobility at palpation etc. In these cases it is of particular interest to notice otomicroscopically if the tympanic membrane is movable during Toynbee's or Valsalva's tests, i.e. if there is air passage from the tube to the labyrinth windows or if there are fibrous adhesives between the drum and the medial tympanic wall in a substantial part of the middle ear. Ingelstedt's and Fliesberg's modification of Siegle's speculum using plain glass without magnification is a very useful otomicroscopical accessory. It makes it easy to observe the mobility of different parts of the drum and malleus as well as the axis of the movements of malleus.

CLINIC

During the preoperative otomicroscopic examination and the evaluation of the middle ear function it is, of course, necessary to study the transmission mechanism from pathological-anatomical point of view as well as concerning the hearing to find an adequate basis for treatment and prognosis. When the isolated case is examined such a variation is found both pathologic anatomically and functionally that one can scarcely predict the indication for an otosurgical performance on the basis of a general knowledge of the transmission. In spite of these variations and of the presence of clinical cases, which are on the whole very difficult to penetrate and evaluate, it is useful to mention some empirically found types of conductive deafness.

When the cases with conductive deafness are

II CLINICAL INVESTIGATIONS

THE ROLE OF OTOMICROSCOPY IN THE ASSESSMENT OF CONDUCTIVE DEAFNESS

To get a view as to what extent the otomicroscopy and various functional tests can be clinically utilized and evaluated, 100 cases of conductive deafness, consecutively admitted to the audiological unit for preoperative examination were studied. Cases of otosclerosis were not included, since the otoscopical findings, as a rule, are normal in these cases. (Lundborg, Lindzander Lindström 1969)

Tab 1 shows the case material, consisting of chronic otitis with central perforation, chronic otitis with marginal perforation, residue, adhesive chronic otitis etc and how in the different groups of typecases the otomicroscopy and certain functional and audiometrical methods could be utilized in the evaluation of the conductive deafness cases. The number of cases examined in the different groups, of course,

depends on to what extent different methods are applied, which explains the figures presented. The evaluation of these findings and test results have formed the basis for an indication of either myringoplasty tympanoplasty eventually together with a reconstruction of chain, "conservative atticotomy etc. Explorative tympanotomy has been performed in conductive deafness cases without clear etiology to find out whether the ossicular chain is interrupted or defective for instance as a result of posttraumatic lesion or as a consequence of congenital malformation. In cases, where an operative indication was not considered, a hearing aid was prescribed according to normal rules

(The table possibly reflects a somewhat conservative surgical attitude compared with the conception of certain other clinical staffs.)

The survey demonstrates that otomicroscopy in relation to other examinations and tests was considered to be the most valuable element as a basis for diagnosis. The same tendency is reflected in the whole case material, on which this work is based (ca. 1000 cases)

Table 1 Transmission testing in 100 cases of chronic otitis etc and its clinical usefulness

stapes ("tympanostapediopexy") Stapes thus acts as a columella, substituting the rest of the ossicular chain. In certain cases this results in a closed gap. Tympanoplastics are technically performed in many different ways. Many types of columellas are utilized and the results vary. There are certain conditions, which sometimes contradict a tympanoplasty for instance excessive cholesteatoma, pronounced hyperplasia of the middle ear mucosa, adhesives in the tubar portion of the middle ear etc.

See Case X XI

3 Chronic otitis with marginal perforation

Occasionally the hearing may be influenced very little by small perforations in the attic or central part of the drum in spite of excessive granulation and cholesteatoma around the ossicles. The primary task in such cases is to remove inflammatory tissues from the ear. All such tissues, for instance otitis, cholesteatoma etc. have to be removed by an atticotomy - conservative if possible. In cholesteatoma cases one often has to resect caput mallei. If a certain continuity of the ossicular chain thus may be conserved, there is occasionally a fairly good transmission and a clinical healing of the inflammatory processes. In other cases incus has to be extracted. The changes mainly influence sound conduction in these cases. The earlier method of choice in connection with chronic otitis, when a radical cavity was created, to a certain extent can be substituted by the above mentioned more conservative performance.

See Case XII

4 Chronic adhesive otitis. Often the drum is atrophic, collapsed and to various extent also ad-

herent to the promontory wall. The ossicular chain is rigid and sometimes defective, for instance by luxation of incudostapedial joint as a result of transudate organisation. The cause is often an impaired tubar function. The conductive hearing loss varies, depending upon the degree of drum mobility etc. The changes are mainly influencing sound collection and sound conduction. Because of the bad tubar function and a pronounced tendency to form adhesives, it is often not possible in these cases to create a normal, mobile middle ear.

See Case V VI

5 Chronic residuous otitis with drum scars and defects of ossicular chain. There are cases like the end result of an inflammatory process in appearance which have a traumatic genesis. Direct violence towards the drum and ossicles can result in luxation or lesion of incus. In connection with blows and pressure from the sides of the skull and also in connection with mastoidectomies, incus may be luxated in a similar way. In such cases there may be a maximal conductive deafness (50-60 dB) because the changes are influencing sound collection, sound conduction and sound protection as well. If the drum (scar) is thin, the incus lesion may be diagnosed otomicroscopically. There are functional tests giving additional information concerning possible ossicular chain defects. Often a tympanotomy is indicated. If processus longus incudis is defective but stapes is found anatomically normal and movable in the oval window at palpation, a tympanostapediopexy may reconstruct the transmission and give permanent results under certain conditions.

See Case IV

II CLINICAL INVESTIGATIONS

THE ROLE OF OTOMICROSCOPY IN THE ASSESSMENT OF CONDUCTIVE DEAFNESS

To get a view as to what extent the otomicroscopy and various functional tests can be clinically utilized and evaluated, 100 cases of conductive deafness, consecutively admitted to the audiological unit for preoperative examination were studied. Cases of otosclerosis were not included, since the otoscolopical findings, as a rule, are normal in these cases. (Lundborg, Lindzander Lindström 1969)

Tab. 1 shows the case material, consisting of chronic otitis with central perforation, chronic otitis with marginal perforation, residue adhe-siv chronic otitis etc. and how in the different groups of typescases the otomicroscopy and certain functional and audimetrical methods could be utilized in the evaluation of the conductive deafness cases. The number of cases examined in the different groups, of course,

depends on to what extent different methods are applied, which explains the figures presented. The evaluation of these findings and test results have formed the basis for an indication of either myringoplasty tympanoplasty eventually together with a reconstruction of chain, "conservative" atticotomy etc. Explorative tympanotomy has been performed in conductive deafness cases without clear etiology to find out whether the ossicular chain is interrupted or defective for instance as a result of posttraumatic lesion or as a consequence of congenital malformation. In cases, where an operative indication was not considered, a hearing aid was prescribed according to normal rules.

(The table possibly reflects a somewhat conservative surgical attitude compared with the conception of certain other clinical staffs.)

The survey demonstrates that otomicroscopy in relation to other examinations and tests was considered to be the most valuable element as a basis for diagnosis. The same tendency is reflected in the whole case material, on which this work is based (ca. 1000 cases)

THE CLINICAL APPLICATION (Documentation and Discussion)

In order to give a medically well based service to those large groups of patients for whom—at the first examination—either otosurgery or hearing aid ordination seem adequate different institutions achieved various solutions concerning arrangements for the patients. Because there is a considerable overlapping by these major patientgroups, this offers a certain problem of organisation. According to the authors' experience, gained during a number of years, this task can be fruitfully approached by the departments of otology and audiology in close co-operation. At regular staffmeetings the test results from the cases of the week are demonstrated and recommendations are made concerning otologic and audologic measures. A clearly arranged statement of the performed examinations is necessary both from clinical and didactical point of view. In connection with the otomicroscopy it is of particular value to illustrate the findings from drum and middle ear by sketches on stencilled patterns and by color photos of the otoscopic findings. To gain time, surveyability and uniformity in the evaluation of cases, the findings of examination are presented in special journals, from which diagnoses in the size of 70×70 mm easily are made, using a reproducing apparatus (Polaroid Copymaker). Within the frame of these slides, color copies in the size of 20×20 mm can be applied. Magnified machine made paper copies in color are included in the journals.

To get an uniformity in connection with the establishment of operative indication in cases with conductive deafness it has proved to be necessary to demonstrate and discuss continuously a large number of cases within the staff. This further emphasizes the need of a documentation of the otoscopic findings together with the functional tests etc.

A photographic documentation of the otoscopic findings is an ideal method for high-

fidelity recording of current data because the demonstration simplifies the situation for all staff members. Its availability for follow-up studies also offers practical advantages. These findings can be compared with functional tests in order to study the functional significance of various morphological findings. The functional loss, caused by various pathologic changes in the drum, the ossicular chain, middle ear mucosa etc. is often not clearly understood.

At the examination of the individual case and during the observation of pathologically changed middle ear structures, in our discussions one has tried to compare those findings with the audiograms and other functional tests. It seems clinically meaningful—as is already mentioned—to evaluate simultaneously which of the clinically comprehensible elements of the conductive mechanism—i.e. the sound collection, the sound conduction and the sound protection—that are pathologically changed, requiring correction.

Because essential physiological knowledge concerning the normal as well as the diseased conductive mechanism has been gained clinically by means of preoperative examinations, otosclerosis surgery, reconstructive otosurgery in cases with chronic otitis etc. it seems fruitful to continue this work, following a clinical conception by "critical observations of human physiopathology" (V. Goodhill). For a number of years the oto-audiological team has been working in accordance with the approach sketched above (observation, documentation and discussion). This, as we believe, has been a positive experience and therefore a brief survey may be of some interest.

THE OTOMICROSCOPICAL EQUIPMENT AND PHOTOTECHNIQUE

Making photos with the original types of otomicroscopes offered many difficulties and pictures of acceptable quality were rare. Long ex-

posure times were required with the light sources and films available and the pictures became unsharp, because the patient did not remain still. Further it was not possible to choose a diaphragm aperture small enough to get sufficient depth of field. Elaborate otomicroscopical systems were developed by Schultz van Treck (1947), Kobrak (1956) and others, but only for special laboratory conditions and special purposes, not for clinical routine work.

Principally the authors' aim was to take photos during the ordinary otomicroscopic examination in order to develop a routine technique used as a standard clinical performance. Therefore a modern stereoscopic otomicroscope with light supply through the lens system was the first prerequisite.

Attempts to take black & white pictures with a Polaroid camera applied on one of the oculars of a Zeiss microscope, only occasionally gave usable results and with the sacrifice of binocular orientation.

The film is very sensitive (A.S.A. = 3000) but pictures were found to be of too little contrast, which made the observation of fine structures difficult.

The next step in order to get more informative pictures was to try color photography. Polaroid Color Film, however, is too unsensitive (A.S.A. = 75) and satisfactory results were not obtained with that film.

Thus a color film of sufficient sensitivity was another prerequisite. Kodak High Speed Ektachrome Type B color reversal film (E.A.B. = 135-20) was found to be suitable (A.S.A. = 125).

The commercially available Beam splitter* (Code 301513) and "Photoadapter" (Code 301517) constituted important accessories for the application of cameras on a Zeiss operation microscope. The light supply of the ordinary equipment however with its 50 W lamp, as a rule offered insufficient illumination through the ear speculum on the drum and middle ear structures.

Therefore some new constructions had to be made.

1 The ordinary lamp was replaced by a halogen projection lamp of 250 W.

2 This lamp was put in a new lamphouse, equipped with a spherical mirror.

3 A device making it possible to overvolt age the lamp during a very short moment (29 V 1/10 sec.) By means of another device a synchronized impulse is given to an electrically conducted shutter resulting in maximal illumination only during the required exposure time.

4 A cooling fan for the lamphouse.

5 The ear speculums were painted grey to resemble the reflex conditions of the skin. This was done to facilitate the machine copying. A speculum with very high (shiny) or very low (black) reflection will give too high light contrast for the copying machine to handle. The colored paper copies are not, as a rule, of the same quality as the diapositives, but they are useful in the journals etc.

The Contarex S camera housing offers the possibility to apply a special identification strip for each patient. The strip is put in the camera in direct contact with the film, and the patient's initials etc. written upon it will be copied in each film.

In order to raise the quality of the photography further trials are being made with electronic flashlight. The problem in this connection is to get the light into the condenser system.

Especially for photography during operation a motordriven filmtransport in the camera would be convenient.

With the present equipment an exposure time of 1/30 sec. and a diaphragm aperture at the photoadapter of 1/22 are chosen. Using these

values one is getting acceptable results in terms of exposure, depth of field and freedom from unsharpness due to movements of the patient. Further development of the method however will make it possible to use a shorter exposure

time, say 1/125 sec., and a smaller aperture say 1/64 which above all would make the procedure easier and give better results in the hands of photographically unexperienced examiners.

CLINICAL CASE EXAMPLES

Otomicroscopic findings and function

A series of cases with varying middle ear pathology documented by 4-color pictures and corresponding halfshematic black and white sketches with indication of relevant anatomical landmarks will be presented (See legend) The otoscopic observations are com-

pared with audiograms and other clinical and functional investigations. In connection with the discussion of diagnosis and prognosis an evaluation is also made about how the different pathologic changes seem to influence the clinically comprehensible elements of conductive mechanism i.e. sound collection, sound conduction, sound protection.

III GENERAL DISCUSSION AND CONCLUSIONS

THE ACTUALITY OF MIDDLE EAR PROBLEMS

Activities in otology and audiology during the last decades have greatly contributed to the understanding of the function of hearing and of the diagnosis and therapy of deafness.

The clinical work and research within this field are reflected, for instance, in scientific journals and international congress programs. The interest is apparently more focused at cochlear than middle ear problems as it can be seen, for instance, in D.S.H.—Abstracts (Deafness Speech and Hearing Publications) Archives of Otolaryngology and in Berendes—Link Zöllners Handbook, which probably constitute some of the most representative surveys of the fields of interest.

Thus, formulation of questions providing incentives to investigate problems concerning the cochlea seem to have been fruitful. Utilizing different scientific methods (electronmicroscopy electrophysiology cytochemistry microanalysis etc.) many important details of the inner ear's morphology and function have been clarified.

The conditions are not quite the same concerning the middle ear. There have been presented many contributions having clarified the middle ear function and there are positive—sometimes excellent—results from the treatment of different types of conductive deafness. Despite of this many reports and discussions reflect a certain disappointment concerning several parts of otosurgery, the possibilities of maintaining the function of the Eustachian tube etc. From the clinical point of view of course, these obstacles and hesitation have to be overcome.

One reason for this attitude seems to be a discrepancy between the clinical activities and the non-otologic activities using physical and physiological concepts and their application to

the problems of the sound conduction mechanism. Clinicians cannot be expected to consider testresults etc., if these are relating purely physical concepts, often formulated in terms, which are not clearly understood from the clinical point of view.

On the other hand, otology and audiology have revealed clinical evidence of therapeutic measures, which cannot always be clearly interpreted on physical grounds. Such situations should reasonably—with satisfactory cooperation—act as a challenge to research in the theoretical disciplines.

Thus—when an evaluation is made to correlate the observation of middle ear pathology and the hearing loss, expressed in terms of various functional tests—it seems convenient to use clinically comprehensible factors concerning the conductive mechanism and middle ear.

There is clinical evidence from the observations of many individual cases with hearing loss, that these factors, for instance, show great quantitative variations. A case with central drum perforation may according to preoperative evaluation, have a prognosis of 25 dB hearing gain, but the myringoplasty can result in an improvement of 45 dB. On the basis of this examination one can predict the result to be within some kind of level-interval but sufficient exactness is not yet achieved. Therefore many aspects of the sound conduction mechanism under both normal and pathological conditions have to be clarified.

This knowledge seems to be gained by an otomicroscopical approach and investigations of clinical case materials with different types of sound-conductive deafness.

Increased clinical activities with the middle ear
Because of the many functional, diagnostic and therapeutic problems from the middle ear one can expect increased clinical activities dealing with the middle ear and the conductive deafness due to causes arising here.

The case materials with conductive deafness which need investigation and treatment are also

III GENERAL DISCUSSION AND CONCLUSIONS

THE ACTUALITY OF MIDDLE EAR PROBLEMS

Activities in otology and audiology during the last decades have greatly contributed to the understanding of the function of hearing and of the diagnosis and therapy of deafness.

The clinical work and research within this field are reflected, for instance, in scientific journals and international congress programs. The interest is apparently more focused at cochlear than middle ear problems as it can be seen, for instance, in D.S.H.—Abstracts (Deafness Speech and Hearing Publications), Archives of Otolaryngology and in Berendes—Link Zöllner's Handbook, which probably constitute some of the most representative surveys of the fields of interest.

Thus, formulation of questions providing incentives to investigate problems concerning the cochlea seem to have been fruitful. Utilizing different scientific methods (electronmicroscopy electrophysiology cytochemistry microanalysis etc.) many important details of the inner ear's morphology and function have been clarified.

The conditions are not quite the same concerning the middle ear. There have been presented many contributions having clarified the middle ear function and there are positive—sometimes excellent—results from the treatment of different types of conductive deafness. Despite of this many reports and discussions reflect a certain disappointment concerning several parts of otosurgery the possibilities of evaluating the function of the Eustachian tube etc. From the clinical point of view of course, these obstacles and hesitation have to be overcome.

One reason for this attitude seems to be a discrepancy between the clinical activities and the non-otologic activities using physical and physiological concepts and their application to

the problems of the sound conduction mechanism. Clinicians cannot be expected to consider testresults etc., if these are relating purely physical concepts, often formulated in terms, which are not clearly understood from the clinical point of view.

On the other hand, otology and audiology have revealed clinical evidence of therapeutic measures, which cannot always be clearly interpreted on physical grounds. Such situations should reasonably—with satisfactory cooperation—act as a challenge to research in the theoretical disciplines.

Thus—when an evaluation is made to correlate the observation of middle ear pathology and the hearing loss, expressed in terms of various functional tests—it seems convenient to use clinically comprehensible factors concerning the conductive mechanism and middle ear.

There is clinical evidence from the observations of many individual cases with hearing loss, that these factors, for instance, show great quantitative variations. A case with central drum perforation may according to preoperative evaluation, have a prognosis of 25 dB hearing gain, but the myringoplasty can result in an improvement of 45 dB. On the basis of this examination one can predict the result to be within some kind of level-interval but sufficient exactness is not yet achieved. Therefore many aspects of the sound conduction mechanism under both normal and pathological conditions have to be clarified.

This knowledge seems to be gained by an otomicroscopical approach and investigations of clinical case materials with different types of sound-conductive deafness.

Increased clinical activities with the middle ear
Because of the many functional, diagnostic and therapeutic problems from the middle ear one can expect increased clinical activities dealing with the middle ear and the conductive deafness due to causes arising here.

The case materials with conductive deafness which need investigation and treatment are also

expected to become more numerous, though antibiotics have made acute middle ear affections less frequent. (Chronic middle ear cases, on the other hand seem to appear with about the same frequency.) According to clinical experience there are several reasons, that the following middle ear affections will occur more frequently

- a) allergic middle ear manifestations
- b) middle ear malformations on toxic or teratogenous grounds
- c) traumatic middle ear lesions from traffic accidents
- d) middle ear tumors discovered because of increased activity in diagnosis and therapy
- e) latent middle ear affections with adhesive and osteitic processes from the use of antibiotics
- f) aero-otitis because of the successive increase of air-born transportation. Cases with hyperemia, transudation or bleeding may result in adhesive processes

All the above mentioned conditions and clinically manifested tendencies will require an increased use of otomicroscopy together with all available accessories. These activities will probably ameliorate the investigation technique by developing new instruments and methods. This may represent, what Kobrak describes as an "M D-otology" besides a purely theoretical "Ph D-otology"

CLINICAL EXPERIENCES AND INVESTIGATIONS

Some clinical experiences from the oto-audiological team work (consisting of totally 50 ENT specialists including junior doctors in postgraduate training) are referred to

1 An important part of this work has been to examine and evaluate conductive hearing loss cases. It has turned out, that there is a substantial overlapping by two major patient groups: those cases to be operated upon and those needing hearing aids. It is also found,

that with conventional examination technique, using ear speculas without magnification, even experienced otologists may overlook clinically important middle ear details. Thus these factors represent a certain problem of organization.

2 A most valuable instrument required in this clinical work is the meticulous otomicroscopy. It was documented by a detailed analysis of 100 consecutively examined cases, admitted for evaluation of conductive deafness (except otosclerosis) that otomicroscopy revealed to be the essential part of the investigation as a basis for diagnosis. Different functional tests provided supplementary information in part of the cases.

3 Experience has shown, that both for clinical and for didactic reasons, documentation and presentation of essential facts from the investigations of hearing loss patients have to be presented continuously at regular staff meetings.

4 These two basic requirements were the incentives to develop a routine technique for color photography of otomicroscopical findings to be used as a standard clinical tool. The new commercially available, photoaccessories to Zeiss operation microscope and new types of films with sufficient sensitivity constituted important steps toward getting acceptable pictures. The main problem is still to get sufficient light through the ear speculum on the drum and middle ear which is not as a rule possible with the ordinary 50 W lamp. This has to be replaced by a device of our own construction, utilizing a halogen lamp of 250 W and also a fan to neutralize the heat production etc. The ear speculas are painted grey in such a way that light reflection resembles that of the skin, which permits an automatic production of colored papercopies to be used in the journals.

5 The aim of the clinical discussion where the pictures constitute a detail is to document the otoscopic findings and correlate them with various functional tests.

Emphasized by Kobrak it is very difficult in diseased ears, to assess the different physical factors of sound conduction as to their individual role in causing hearing loss. So far at

tempts with this aim in mind do not seem to have been fruitful. On the other hand, it seems clinically meaningful to combine the observation of changed and damaged middle ear details with an evaluation of how pathology may influence the conductive apparatus concerning its clinically comprehensible functions, *i.e.*

- sound collection
- sound conduction
- sound protection

With an experience of a substantial case material, discussed and evaluated in this way this technique has been found to be useful in the clinical work and for didactic purposes. This type of documentation makes it possible to demonstrate the essential facts from a large group of patients during few conference hours.

The slides with transparent color pictures and the journals with sketches and paper copies in color form such a good basis for clinical decisions that additional visits of the patients to the clinic for further inspection etc. are often not necessary.

Development of the otomicroscopic approach. Otomicroscopical observations of middle ear conditions will probably be still further utilized as a correlate to different diagnostic and therapeutic measures, thus contributing to the simplification of these methods. During the last decades many steps forward have been made concerning the otomicroscopical technique and also the mode of working.

Therefore the next step in this development should be the construction of a suitable otomicroscope which could make the otomicroscopic approach a standard in most clinical work. The pictures, presented here, are produced by amateurs and they constitute principally a clinical aid. With elaborate, well fitted equipment, it is reasonable to assume that otomicroscopical photos will be a requisite in the journals just like audiograms and other test results. It also seems likely that such an otomicroscopic approach in the clinical work will become an incentive to research of the middle ear with all possible methods.

SUMMARY

In the oto-audiological cooperation there is a substantial overlapping between two major groups of patients, those needing a hearing aid and those needing otosurgery according to the primary examination. This fact means a certain problem of organization.

The otomicroscopical examination has turned out to be a most useful instrument in this connection. In 100 cases of conductive deafness (except otosclerosis) the otomicroscopic findings revealed to be essential for the diagnosis in the great majority of cases. The functional tests, performed, are giving supplementary diagnostic information in part of the cases.

Both from clinical and didactic reasons documentation of the otomicroscopic findings is necessary and the clinical discussion requires simultaneous presentation of these findings together with the results from various clinical and functional tests.

This clinical praxis was the incentive to develop a routine technique for color photography of the otomicroscopic findings from the drum and middle ear which could be made by means of some special accessories to a Zeiss operation microscope.

A series of cases with different conductive pathology are presented. The observations of the otomicroscopical findings are correlated with the audiograms and functional tests.

An evaluation is also made of how pathology has changed the clinically comprehensible elements of the conductive mechanism—the sound collection, the sound conduction and the sound protection.

To raise the quality of otoscopy it seems meaningful to construct a suitable otomicroscope with photo equipment to be used in most clinical work. The present work has shown, that even with an equipment, partly consisting of accessories, made in the laboratory of the audiological unit, this technique can be clinically utilized.

This also forms a basis for a more functional-

clinical approach at the assessment of cases with conductive deafness

ZUSAMMENFASSUNG

Die Mehrzahl der Fälle mit Mittelohrschwerhörigkeit lässt sich hinsichtlich ihrer Behandlungsmöglichkeiten in zwei grossen Gruppen zuordnen. Das sind einmal die Fälle für die eine Operation die gegebene Indikation ist, und zum andern die Fälle für die ein Hörgerät die gegebene Hilfe ist. Zwischen diesen beiden Gruppen findet sich jedoch eine recht grosse Reihe von Fällen bei denen es sehr schwierig ist, von der primären Untersuchung her in dieser Hinsicht eine Entscheidung zu treffen. In diesen Fällen hat sich die otomikroskopische Untersuchung als ein für die Diagnose sehr wesentliches Komplement erwiesen.

In einer Eingangsstudie von 100 Fällen von Mittelohrschwerhörigkeit (unter denen sich wohlgeordnet keine Otosklerosefälle fanden) konnte dies in der grossen Mehrzahl der Fälle durch die otomikroskopischen Befunde klar gezeigt werden. Im Zusammenhang damit wurden ausserdem Funktionsprüfungen durchgeführt, aus denen zusätzlich diagnostische Aufschlüsse erhalten werden konnten.

Um in der klinischen Diskussion die otomikroskopischen Befunde gleichzeitig mit den Resultaten der klinischen und funktionellen Untersuchungen zugänglich zu haben wurde eine spezielle Aufnahmeapparatur entwickelt, mit der es möglich war Farbphotographien von den otomikroskopischen Befunden vom Trommelfell und Mittelohr zu machen. Als Aufnahmeinstrument diente ein Operationsmikroskop der F. Zeiss mit eigens konstruierten Zusatzrichtungen u. a. um die Beleuchtungsstärke in dem erforderlichen Masse zu erhöhen.

Ca. 1000 Fälle mit unterschiedlicher Mittelohrpathologie wurden auf diese Weise untersucht. Eine Reihe von diesen Fällen werden näher gezeigt und ihre otomikroskopischen Befunde mit den Tonaudiogrammen und Funktionsprüfungen korreliert. Des weiteren werden die Auswirkungen der pathologischen Veränderungen im Mittelohr auf den Schalleitungsmechanismus und den Schallschutz des Ohres erörtert.

Aus den vorliegenden Untersuchungen dürfte zur Genüge hervorgehen, dass es zur Verbesserung der otomikroskopischen Untersuchungsmöglichkeiten sehr zu begrüssen wäre ein entsprechendes Standardmikroskop mit den notwendigen Photomöglichkeiten in der routinieklinischen Arbeit zugänglich zu haben.

I Introduction and aim of present investigation

Recording of spontaneous or induced nystagmus with the aid of electro-nystagmography is an essential part of modern neuro-otological examination. In the living human eye an electrical potential difference can be recorded between the anterior and posterior segments of the eye. Thus, with two recording electrodes suitably positioned in contact with the skin near the lateral canthi of the lids of the two eyes movements of the eyes can be recorded as a result of alterations in the electrical field of the surrounding conducting media. On the other hand, the fact that the voluntary eye movements performed are constant in magnitude and direction provides the possibility of recording a constant fraction of the corneo-fundal potential (electro-oculogram, EOG). It has been suggested that in the healthy human eye the corneo-

fundal potential may show considerable spontaneous variation. It is also well known that typical changes in the level of the corneo-fundal potential can be produced by changes in retinal illumination. Therefore the amplitude of the electro-nystagmogram (ENG) is influenced not only by the amplitude of the nystagmus to be examined, but also by the level of the corneo-fundal potential difference at the moment of recording.

In the present study the magnitude of spontaneous variation in the corneo-fundal potential (EOG) as well as the effects of constant periods of darkness and illumination on its amplitude have been investigated in order to determine what are, for this purpose, adequately reliable conditions for clinical recording of the electro-nystagmogram.

II Earlier investigations

1 Site of origin of the corneo-fundal potential

In the living eye an electrical potential difference can be recorded between the cornea and the posterior pole of the eye. It has been known since the time of Du Bois REYMOND (1849) that in vertebrates the cornea is positive in respect to the fundus whereas in invertebrates (DEWAR and MC KENDRICK 1876) the potential gradient is reversed. This suggests that this potential difference (standing potential corneo-fundal potential) is generated in the retina. Later this view was confirmed by the finding of an abrupt alteration in the potential at the lateral edge (ora serrata) of the retina (de HAAS 1903 as quoted by KOHLRAUSCH 1931). It was also confirmed that an equally large potential difference could be recorded across the isolated retina and across the unopened eye (KÜHNE and STEINER 1881).

Recently NOELL (1953) has shown that drugs which selectively alter the standing potential can be shown to cause extensive damage in the pigment epithelium. It is also evident from the micro-electrode studies of BRINDLEY (1956a) as well as of BROWN and WIESEL (1958) that one of the charged membranes in the retina across which a large potential difference is generated can be localized in the pigment epithelium.

In the human eye a fraction of the corneo-fundal potential difference can be recorded with electrodes placed on the skin on both sides of the eye and then rotating the eye in the plane of the electrodes through a constant angle. It has been shown that the amplitude of this eye movement potential bears a simple relationship to the degree of rotation of the eyes (FENN and HURSH 1937, LEKSELL 1939).

This provides us with a relatively accurate

method of measuring eye movements. On the other hand the same method can be applied as a clinical test (ARDEN and KELSEY 1962a) to measurements of the functional state of the pigment epithelium. In pathological conditions for example pigment degeneration of the retina and detachment of the retina the clinical record of the corneo-fundal potential shows an abnormally low amplitude and the light induced increase in the amplitude of this potential is defective (ARDEN, BARRADA and KELSEY 1962). These authors concluded that in order to obtain a normal electro-oculogram the following are required: functioning receptors, a functioning pigment epithelium, contact between the neural structures of the retina and the pigment epithelium as well as adequate choroidal and retinal blood supplies. Light that evokes an increase in the amplitude of the corneo-fundal potential generated in the pigment epithelium is probably absorbed in the retinal receptors. This view is supported by the spectral sensitivity measurements of the light induced increase in the corneo-fundal potential performed by ELIENIUS and LEHTONEN (1962) and ELIENIUS and KARO (1966).

In addition to the corneo-fundal potential generated in the pigment epithelium smaller potential differences can be recorded in the anterior segment of the eye (cornea, aqueous, ciliary body, LERHMANN and MEESMANN 1924, POTTS and MODRELL 1957, STEPANIK 1958) or between the anterior and posterior poles of the lens (BRINDLEY 1956b).

2 Effects of illumination and darkness on the amplitude of the electro-oculogram of the human eye

It has been known since the work of KÜHNE

and STEINER (1881) as well as HIASTEDT and NARIEL (1902 as quoted by KOHLHAUSCH 1931) that illumination alters the potential difference which in animal eyes can be directly recorded between the cornea and the posterior pole of the eye. In the human eye MILES (1940) made systematic studies on the effects of rapid changes of illumination on the amplitude of the EOG. He found that this amplitude was practically constant in constant illumination, whereas reduction in illumination by three logarithmic units decreased the amplitude by 10 per cent within 5 minutes and by 20 per cent within 10 minutes. On the other hand an increase in illumination to the previous level (5 mLa) increased the amplitude of the EOG by 43 per cent above the value previously recorded after 10 minutes in the dark. Correspondingly ASERINSKY (1955) found that after 10 minutes illumination the amplitude of the EOG was increased by 11 to 208 per cent above the value measured after an equally long period in the dark. ASERINSKY (1955) also found that when the eye was stimulated by a succession of alternating periods of illumination and darkness the amplitude recorded after the second period in the dark was significantly smaller than after the first period in the dark. However after several dark (and light) periods a constant level of maximum amplitude was obtained. On the other hand, after long period in the dark (sleeping over night in darkness) the amplitude of the EOG recorded early in the morning was found to be 29 to 51 per cent larger than the amplitude previously measured in the evening at the end of the second short period of dark-adaptation. In agreement with MILES (1940) and ASERINSKY (1955) TEN DOESCHATE and TEN DOESCHATE (1956) found that the amplitude of the EOG decreased during dark-adaptation and increased during light-adaptation while the results of FRANCOIS, VERRIEST and DE ROUCK (1955) suggest that in this respect the effects of light and darkness on the EOG are totally reversed. Using longer periods of dark-adaptation than

previous authors TEN DOESCHATE and TEN DOESCHATE (1956) were also able to detect a secondary slow increase in the amplitude of the EOG after the minimum found on the average after 10 minutes in the dark. This is in agreement with the theory put forward by KRIS (1958) and KOLDER (1959) that the effects of light on the EOG resemble a process of damped oscillation of this potential. In the human eye the peak and trough times of these oscillations occur within the following ranges: first peak at $10 \text{ min} \pm 2 \text{ min}$, first trough at $25 \text{ min} \pm 4 \text{ min}$ and second peak at $36 \text{ min} \pm 4 \text{ min}$ (KRIS, 1958). The amplitude of the first peak varies with the logarithm of retinal illumination and with the duration of preliminary dark adaptation (ARDEN and KELLEY 1962b). Only the size of the first peak depends on the intensity of illumination, while the amplitude of the second and third peaks and the amplitude of the trough do not vary with the intensity of illumination (KOLDER, 1959). A logarithmic relationship between the energy of the light stimulus and the light-induced increase in the amplitude of the rabbit's EOG was reported by HICK and PAPET (1957).

Recently KOLDER and BRECHER (1966) have contributed to the understanding of the oscillating nature of the alterations in the amplitude of the human EOG induced by light and darkness by describing in addition to the slow oscillatory process another type of oscillation of much higher frequency. They showed that the slow oscillatory process of the indirectly recorded human corneo-fundal potential can be brought into synchrony when the eye is stimulated with repeated light and dark phases of equal duration (12.5 minutes). In addition to this slow oscillatory process (one period lasting 25 to 30 minutes) a transient fluctuation of the corneo-fundal potential follows immediately upon a change from light to dark or from dark to light. This initial transient fluctuation has been previously described (ASERINSKY 1955, KRIS, 1958, KOLDER 1959, ARDEN and KELLEY 1962a). KOLDER and BRECHER (1966)

showed that a fast oscillatory process of the corneo-fundal potential can be evoked by stimulation with repeated short periods of light and darkness and can be brought into synchrony with light and dark periods of equal duration (11 minutes). As compared with the slow oscillatory process the fast oscillations are opposite in direction the change in the amplitude being reduced by illumination and increased by darkness.

3 Spontaneous variation in the amplitude of the electro-oculogram of the human eye

There are several reports showing the large individual variation in the amplitude of the EOG (MOWBRER RUCH and MILLER 1936 FENN and HURSH 1937 MILES 1939 MACKENZIE and HARDER 1954 FRANCOIS VERRIEST and DE ROUCK 1956 KOLDER 1959 SILACKEL 1960 ARDEN and BARRADA 1962 ELENIUS and KARO 1966). In 52 healthy subjects examined by ARDEN and BARRADA (1962) the range of variation in the amplitude of the light peak potential was reported to be 15.3 to 66.7 $\mu\text{V}/\text{degree}$ of eye rotation (high illumination 3000 troland) and 14.0 to 80.0 $\mu\text{V}/^\circ$ (low illumination 350 troland) respectively. Correspondingly in ten subjects examined by ELENIUS and KARO (1966) the average light peak amplitude (obtained after 8 minutes of illumination with blue light of 330 000 photopic troland intensity) was found to be 1.5 mV/45 degrees of eye rotation (33.3 $\mu\text{V}/^\circ$) the extreme individual values being 0.85 and 2.25 mV/45° (18.8 and 50 $\mu\text{V}/^\circ$). A review of the results of earlier work in this field based on measurements made with widely differing recording techniques (re-calculated in μV) was published by ARDEN and BARRADA (1962).

FENN and HURSH (1937) and MILES (1939) as well as MACKENZIE and HARDER (1954) found variations of the order of 50 per cent

(increase or decrease) in the amplitude of the EOG measured in the same subject on two consecutive days. ASERINSKY (1955) observed that a regular increase in the amplitude of the EOG occurred during the night the amplitude measured in the morning being 29 to 51 per cent larger than the amplitude measured the previous evening. This is not in agreement with a report by KRIS (1960) of a regular diurnal variation in the amplitude of the EOG amplitudes being lowest early in the morning and greatly increased (doubled or even trebled) by noon.

DAVIS and SHACKEL (1960) were unable to confirm the results of KRIS (1960). In fact they found that in one subject the amplitude of the EOG changed in the course of the day by as much as 300 μV although in most cases it remained almost unaltered. The variation in the amplitude that occurred within a week was also found to be relatively limited. This variation was on the average 46 μV and less than 105 μV in 95 per cent of cases whereas the variation in the amplitude observed within 24 hours was somewhat larger (on the average 76 μV). A slight reduction in the amplitude of the EOG in the course of the day has been reported by AANTAA and ELENIUS (1968). Their measurements were made at 8 a.m. and 8 p.m. using light induced amplification of the EOG after 8 minutes of illumination with light of 10 000 troland intensity following a period of dark adaptation of 15 minutes duration. In their results the reduction in the amplitude that occurred between 8 a.m. and 8 p.m. was on the average 10 per cent. Stimulation with light was also used by HELSEN (1967) who investigated the variation in the relationship between the light peak and the dark trough of the EOG measured at intervals of one week. No correlation was found in the female subjects of this study between the variation in the ratio (light peak / dark trough $\times 100$) of the EOG and the menstruation or ovulation cycle.

III Methods material and procedure

In most experiments the electro-oculogram was recorded with a condenser-coupled differential amplifier connected to a pen recorder (Electro-nystagmograph, Madson Electronics). The amplification used was $1250 \mu\text{V}/\text{cm}$ and the time constant 2 seconds. Conventional lead electrodes (7 mm in diameter) were used. The electrodes were attached to the skin with adhesive tape, and electrode jelly was used to improve the contact. The ground electrode was attached to the skin of the forehead. In one series of experiments the D.C. differential amplifier of a Tektronix 502 oscilloscope and chlorinated silver electrodes (6 mm in diameter) were used. Calibration of the amplified signal (horizontal eye movement of constant magnitude) was performed by using both amplifier systems simultaneously so that the deflection of the pen recorded on the electro-nystagmograph could be related to the signal amplified by the D.C. amplifier and observed on the oscilloscope screen as well as to the internal calibration of the Tektronix oscilloscope. Most experiments were performed in the routine ENG laboratory. In this room the walls are white and the ceiling matt grey; however even in the day time the room could be made almost dark by drawing curtains over the windows. Two small lamp bulbs were used as fixation lights. The intensity of the fixation lights could be adjusted so that they were visible but not too bright both during illumination and in the dark. The test subjects were trained to make rapid horizontal eye movements on command from one fixation light to the other and they were instructed not to make compensatory head movements. In the experiments made in this laboratory the subjects were in recumbent position with the head slightly elevated on a cushion. Then the subject was in a comfortable position to look at the fixation

lights located on the upper part of the opposite wall. In those experiments in which stimulation with light was used, the white light was produced with a Leitz projector and projected to form a square ($80 \times 80 \text{ cm}$) image on the wall between the two fixation lights. One series of experiments (measurements of the velocity of eye movements) was performed in the dark room of the department of ophthalmology. The walls and ceiling of this room are black and there is no window. In these experiments the subjects were in a sitting position and the fixation lights were located on the opposite wall at the level of the subject's eyes.

The subject tested were both men and women aged 20 to 25. Most of them came from the local Medical School or the Nursery School. Total material consists of 210 subjects (155 women, 55 men). They had all been found on examination to have healthy eyes. Cases with low visual acuity or with errors of refraction exceeding $+2$ or -2 d were excluded and so were cases with apparent heterophoria or squint. The subjects lived fairly regular lives and were not involved in night work during the period of the tests. For dilatation of the pupils Mydrinat eye drops (Orion) were used.

In different series of experiments of the present study there were variations in the amplifiers and electrodes used, in the magnitude of the horizontal eye movement (angle between fixation lights), in the sequence and duration of the dark and light periods employed as well as in the intensity of illumination. Therefore, to facilitate reading some details of the methods and procedure are given or repeated in the beginning of the respective sections on the results.

Diurnal variation in the resistance of the skin was examined by placing one of the lead

showed that a fast oscillatory process of the corneo-fundal potential can be evoked by stimulation with repeated short periods of light and darkness and can be brought into synchrony with light and dark periods of equal duration (11 minutes). As compared with the slow oscillatory process the fast oscillations are opposite in direction the change in the amplitude being reduced by illumination and increased by darkness.

3 Spontaneous variation in the amplitude of the electro-oculogram of the human eye

There are several reports showing the large individual variation in the amplitude of the EOG (MOWRER RUCH and MILLER 1936 FENN and HURSH 1937 MILES 1939 MACKENSEN and HARDER 1954 FRANCOIS VERRIEST and DE ROUCK 1956 KOLDER 1959 SHACKEL 1960 ARDEN and BARRADA 1962 ELENIUS and KARO 1966). In 52 healthy subjects examined by ARDEN and BARRADA (1962) the range of variation in the amplitude of the light peak potential was reported to be 15.3 to 66.7 $\mu\text{V}/\text{degree}$ of eye rotation (high illumination 3000 troland) and 14.0 to 80.0 $\mu\text{V}/^\circ$ (low illumination 350 troland) respectively. Correspondingly in ten subjects examined by ELENIUS and KARO (1966) the average light peak amplitude (obtained after 8 minutes of illumination with blue light of 330 000 photopic troland intensity) was found to be 1.5 mV/45 degrees of eye rotation (33.3 $\mu\text{V}/^\circ$) the extreme individual values being 0.85 and 2.25 mV/45° (18.8 and 50 $\mu\text{V}/^\circ$). A review of the results of earlier work in this field based on measurements made with widely differing recording techniques (re-calculated in $\mu\text{V}/^\circ$) was published by ARDEN and BARRADA (1962).

FENN and HURSH (1937) and MILES (1939) as well as MACKENSEN and HARDER (1954) found variations of the order of 50 per cent

(increase or decrease) in the amplitude of the EOG measured in the same subject on two consecutive days. ASERINSKY (1955) observed that a regular increase in the amplitude of the EOG occurred during the night the amplitude measured in the morning being 29 to 51 per cent larger than the amplitude measured the previous evening. This is not in agreement with a report by KRIS (1960) of a regular diurnal variation in the amplitude of the EOG amplitudes being lowest early in the morning and greatly increased (doubled or even trebled) by noon.

DAVIS and SHACKEL (1960) were unable to confirm the results of KRIS (1960). In fact they found that in one subject the amplitude of the EOG changed in the course of the day by as much as 300 μV although in most cases it remained almost unaltered. The variation in the amplitude that occurred within a week was also found to be relatively limited. This variation was on the average 46 μV and less than 105 μV in 95 per cent of cases whereas the variation in the amplitude observed within 24 hours was somewhat larger (on the average 76 μV). A slight reduction in the amplitude of the EOG in the course of the day has been reported by AANTAA and ELENIUS (1968). Their measurements were made at 8 a.m. and 8 p.m. using light induced amplification of the EOG after 8 minutes of illumination with light of 10 000 troland intensity following a period of dark adaptation of 15 minutes duration. In their results the reduction in the amplitude that occurred between 8 a.m. and 8 p.m. was on the average 10 per cent. Stimulation with light was also used by KELSEN (1967) who investigated the variation in the relationship between the light peak and the dark trough of the EOG measured at intervals of one week. No correlation was found in the female subjects of this study between the variation in the ratio (light peak / dark trough $\times 100$) of the EOG and the menstruation or ovulation cycle.

III Methods material and procedure

In most experiments the electro-oculogram was recorded with a condenser-coupled differential amplifier connected to a pen recorder (Electro-nystagmograph, Madsen Electronics). The amplification used was $1250 \mu\text{V}/\text{cm}$ and the time constant 2 seconds. Conventional lead electrodes (7 mm in diameter) were used. The electrodes were attached to the skin with adhesive tape and electrode jelly was used to improve the contact. The ground electrode was attached to the skin of the forehead. In one series of experiments, the D.C. differential amplifier of a Tektronix 502 oscilloscope and chlorinated silver electrodes (6 mm in diameter) were used. Calibration of the amplified signal (horizontal eye movement of constant magnitude) was performed by using both amplifier systems simultaneously so that the deflection of the pen recorded on the electro-nystagmograph could be related to the signal amplified by the D.C. amplifier and observed on the oscilloscope screen as well as to the internal calibration of the Tektronix oscilloscope. Most experiments were performed in the routine ENG laboratory. In this room the walls are white and the ceiling matt grey, however even in the day time the room could be made almost dark by drawing curtains over the windows. Two small lamp bulbs were used as fixation lights. The intensity of the fixation lights could be adjusted so that they were visible but not too bright both during illumination and in the dark. The test subjects were trained to make rapid horizontal eye movements on command from one fixation light to the other and they were instructed not to make compensatory head movements. In the experiments made in this laboratory the subjects were in a recumbent position, with the head slightly elevated on a cushion. Thus the subject was in a comfortable position to look at the fixation

lights located on the upper part of the opposite wall. In those experiments in which stimulation with light was used the white light was produced with a Leitz projector and projected to form a square ($80 \times 80 \text{ cm}$) image on the wall between the two fixation lights. One series of experiments (measurements of the velocity of eye movements) was performed in the dark room of the department of ophthalmology. The walls and ceiling of this room are black and there is no window. In these experiments the subjects were in a sitting position and the fixation lights were located on the opposite wall at the level of the subject's eyes.

The subjects tested were both men and women aged 20 to 25. Most of them came from the local Medical School or the Nursery School. Total material consists of 210 subjects (155 women, 55 men). They had all been found on examination to have healthy eyes. Cases with low visual acuity or with errors of refraction exceeding $+2$ or -2 d were excluded and so were cases with apparent heterophoria or squint. The subjects lived fairly regular lives and were not involved in night work during the period of the tests. For dilatation of the pupils Mydrinat eye drops (Orion) were used.

In different series of experiments of the present study there were variations in the amplifiers and electrodes used, in the magnitude of the horizontal eye movement (angle between fixation lights) in the sequence and duration of the dark and light periods employed as well as in the intensity of illumination. Therefore to facilitate reading some details of the methods and procedure are given or repeated in the beginning of the respective sections on the results.

Diurnal variation in the resistance of the skin was examined by placing one of the lead

electrodes used in the present study on the skin near the temporal canthus of the lids of the left eye. The skin was cleaned by rubbing with cotton soaked in 50 per cent ethyl alcohol and electrode jelly was used to improve contact with the skin; this procedure as well as the location of the electrode thus being identical with that used in most of the other experiments of the present study. The electrode-skin resistance of this single electrode was then measured with a Mingograph (Elema-Schönander) electroencephalograph using a group of twenty EEG electrodes (as in EEG recording) in combination as the other measuring electrode. These electrodes were located on the skin of the skull the skin under each electrode having been drilled so that the combined resistance of the group of electrodes was minimal. A 12-cycle alternating current signal was used for the measurements; the amplitude of the recorded sinusoidal oscillation being proportional to the skin-electrode

resistance of a single electrode (10 mm corresponding to 10 kilo-ohms). A group of 148 subjects (average age 44) was examined before 10 a.m. and another group of 148 subjects (average age 42) was examined after 2 p.m. It was found that the average resistance obtained in the morning was 1.57 kilo-ohms as compared with 1.55 kilo-ohms in the afternoon.

In the present study photometry was carried out with a calibrated luxmeter (Svenska Ljuskultur Stockholm). The luminance (apostilb) of the opposite wall was calculated from the measurements obtained in lux units by multiplying by an approximate reflexion factor of 0.8 (10 apostilb = 1 millilambert). Retinal illumination (troland) is obtained by multiplying the luminance converted to nit units (1 apostilb = 0.318 nit) by the pupil area (mm^2).

The statistical significances were tested by Student's *t* test.

IV Results

1 Amplitude of the electro-oculogram as affected by the position of the recording electrodes

MACKENZIE and HARDER (1954) have shown that the amplitude of the EOG decreases as the distance between the electrodes increases. It is also evident (MOWLER, RUCH and MILLER, 1936; KRIZ, 1960) that maximal amplitude of the EOG is obtained by moving the eyes in the plane corresponding to that of the pair of electrodes.

For the purposes of the present study the influence of the location of the electrodes on the amplitude of the EOG was investigated in the eyes of 15 (10 men and 5 women) subjects aged 20 to 25.

Lead electrodes 7 mm in diameter were used. In the original (primary) position the two recording electrodes were placed on the skin near the temporal canthi of the lids of the two eyes (the earthen electrode was placed on the skin of the forehead). In the subjects tested, the distance from the canthi of the lids to the nearest edge of the electrode varied from 14 to 16 mm. In the course of the experiment the position of the recording electrodes was altered by making 1 cm lateral displacements of one or both electrodes. Several recordings of the EOG were made using different electrode positions. The subject was in a recumbent position and, on command, made horizontal 30-degree excursions of the eyes. Two small fixation lights were used to control the magnitude of the movement, as well as to restrict the direction of movement of the eyes to the plane of the electrodes. A condenser-coupled differential amplifier connected to a pen recorder (amplification 1250 μ V/cm, time constant 2 sec) was used. Before beginning the experiment the subject was dark-adapted for 30 min.

The results are shown in Table 1 and Fig. 1. It is evident that the amplitude of the EOG decreases as the distance between the electrodes increases. An increase of 1 cm in the inter-electrode distance (one electrode displaced 1 cm laterally) corresponds to an average decrease in the amplitude of the EOG to 93 per cent of the original level. Analogously a 2, 3 or 4 cm increase in the distance between the electrodes produces an average decrease in the amplitude of the EOG to

Table 1 Amplitude of the EOG with different locations of the recording electrodes

Location of the electrodes	Mean amplitude of the EOG (1 mm corresponds to 125 μ V) and standard deviation as measured in 15 subjects and expressed in per cent of the amplitude recorded by making 30-degree horizontal excursions of the eyes.	Average amplitude of the EOG as percentage of the amplitude recorded with electrodes in the primary position
Near the canthi of the lids of both eyes	Mean 7.21 S.D. 1.27	100
One electrode displaced 1 cm laterally	Mean 7.23 S.D. 1.40	93.8
Both electrodes displaced 1 cm laterally	Mean 6.42 S.D. 1.29	83.3
Lateral displacement of one electrode by 1 cm and the other by 2 cm	Mean 5.53 S.D. 1.10	71.9
Both electrodes displaced 2 cm laterally	Mean 4.63 S.D. 0.85	60.2

Fig. 1. Average amplitude of the EOG (dots, 15 subjects) in μV and as a percentage of the amplitude measured with recording electrodes in the original (primary) position as plotted against laterally increased distance between the electrodes. Vertical bars indicate $2 \times$ standard deviation.

83.72 and 60 per cent of the original level. An increase in the inter-electrode distance of 2 or 4 cm was obtained by symmetrical lateral displacement of both electrodes whereas in order to produce an increase of 1 or 3 cm in the distance one electrode was displaced 1 cm further laterally than the other.

It is interesting to note that for example a decrease in the amplitude of the EOG by an average of 10 per cent below the original level corresponds to an increase in the inter-electrode distance of more than 10 mm. It is most unlikely that an unobserved displacement of the electrodes of this order of magnitude could occur in a series of controlled experiments. In all the subsequent experiments of the present

study in which the same subject was examined on several occasions the location of the electrodes was marked with ink on the skin. Therefore the correct position of the electrodes could be ensured within the limits of 1 mm displacement of each electrode.

2. Electro-oculographic measurements of the velocity of horizontal voluntary eye movement

Measurements of the maximal velocity of a horizontal gaze movement were performed on 10 subjects (5 women and 5 men) aged 20 to 25. Each subject was examined twice on the same day, namely at 8 a.m. and 8 p.m.

Chlorinated silver electrodes and maximal amplification (200 $\mu\text{V}/\text{cm}$) of a D.C. differential amplifier of a Tektronix 302 oscilloscope were used. The velocity of the sweep was 50 msec/cm. Markings made with ink on the skin made it possible to place the recording electrodes in the same position in the morning and in the evening. The subject was seated in a chair. It was checked that compensatory head movements could not be made. A cushion placed behind the head and neck helped to hold the head steady. There were two small fixation lights placed on the opposite wall at the level of the subject's eyes. The distance between the two fixation lights in relation to the distance of the eyes from the wall (260 cm) made an angle of 40 degrees. The subject was instructed to look at the left fixation light and on command to move the eyes straight from the left to the right fixation light. Simultaneously with the command to the right a beam of light was flashed on the right fixation light and a restricted (15 cm diameter) area surrounding it. Part of the same beam was reflected on a barrier layer photocell to produce a triggering pulse for the sweep of the C.R.O. Synchronization of the start of the sweep with the start of the gaze movement greatly facilitated the recordings. On the other hand, the fact that a light signal was flashed on the right fixation light simultaneously with the verbal command to the right aided orientation of the gaze movement.

The recordings were either made directly (visually) from the trace afterglow on the oscilloscope screen or were photographed. One

original recording is illustrated in Fig. 2. All recordings were performed 20 minutes after the beginning of the experiment. The subject spent this preliminary period in a dimly illuminated examination room (2 lux illumination as measured in front of the eyes pupils not dilated) with his eyes closed to acquire a constant state of visual adaptation. Then several recordings were made in rapid succession to obtain a series of at least ten reliable measurements for every case.

The results (averages of ten measurements) are given in Table 2 and show that in the ten cases tested there was no observable difference between measurements made in the morning and in the evening, whereas in individual cases, both in the morning and in the evening, there was a large variation in maximal velocity of the horizontal gaze movement, the extreme values being 71 msec/40 degrees and 100 msec/40 degrees respectively.

3 Light-induced changes in the amplitude of the electro-oculogram

In the first part of the present series of experiments the general effects of light and dark-adaptation on the amplitude of the EOG were examined. It was considered important to know about the effects of the standard illumination of the routine electro-nystagmography laboratory

Fig. 2. An EOG (photographed from the oscilloscope screen) recorded with the aid of a D.C. differential amplifier. The change in the potential level refers to horizontal gaze movement from left to right through an angle of 40 degrees.

Fig. 3 Amplitude of the EOG as measured in the dark (dots) and during illumination (circles). Averages of measurements made on 20 subjects (dots, 0 to 30 min), 10 subjects (dots, 32 to 38 min) and 10 subjects (circles, 32 to 38 min). Vertical brackets show $2 \times$ standard deviation.

room on the amplitude of the EOG recorded after a period in darkness. The experiments were made at different times of day and the subjects came to the examination room from widely differing illumination conditions. A long preliminary period of dark-adaptation was therefore considered necessary. After this period (30 min) the standard illumination of the examination room was turned on and the increase in the amplitude of the EOG was tested in ten subjects, whereas in another series of ten subjects employed as controls the dark-adaptation was continued. The standard illumination of the examination room consists of two series of three (60 cm 20 W) fluorescent tubes mounted uncovered in the ceiling. The matt grey ceiling has a relatively low capacity as a light diffuser, whereas the walls of the room are white. The curtains were drawn over the windows. During the experiments the subjects to be examined were in a recumbent position facing two small fixation lights on the opposite

wall (30 degree angle between the fixation lights). During the period in the dark the subject was asked to keep his eyes closed. Conventional lead electrodes and a condenser-coupled differential amplifier connected to a pen were used for the recordings; the experimental conditions thus being identical to those used in this laboratory for routine ENG recordings.

Twenty women aged 20 to 25 were examined. The pupils were not dilated. The intensity of illumination used in these experiments was 130 lux as measured in front of the eyes with the photocell of a luxmeter placed perpendicularly to the direction of the eyes when looking at the fixation lights. The maximal luminance of the upper part of the opposite wall (above the fixation lights) was estimated to be 25 mLa corresponding to 1000 troland (4 mm average diameter of the pupil during illumination). The luminance of the opposite wall was not uniform and it should also be noted that the six fluorescent tubes placed in the ceiling were

Fig. 4. Amplitude of the EOG measured at the beginning of the experiment and after the following periods: 15 minutes in the dark, 8 minutes of illumination with light of 10 000 troland intensity and 15 minutes in the dark. The dots and the circle show averages of measurements made on 56 subjects; vertical bars show $2 \times$ standard deviation.

within the upper part of the visual field when the subject looked at the level of the fixation lights.

The EOG was recorded every two minutes both in the dark and during illumination. The individual measurements given are average amplitudes of a series of at least ten electro-oculograms recorded. The results are shown in Fig. 3. It is evident from the averages of the results obtained in the ten subjects shown in this illustration (dots, vertical brackets show $2 \times$ standard deviation) that a steady amplitude of the EOG is not achieved. In the dark there is first a reduction in the amplitude of the EOG followed after 10 to 12 minutes by a secondary increase which approaches its maxi-

mum after 24 to 26 minutes in the dark. Then the amplitude again shows a slow decrease. In the ten subjects tested during illumination as well (circles, vertical brackets show $2 \times$ standard deviation) there is a definite increase in the amplitude above the level measured in the ten controls continuously tested in the dark.

The average minimum amplitude obtained after 8 minutes in the dark is 32 per cent below the level of the amplitude measured at the beginning of the experiment. The average maximum amplitude obtained 8 minutes after stimulation with light (38 minutes after the beginning of the experiment) is 39 per cent above the level measured at the beginning of the experiment. It is thus evident that considerable

Fig 3 Amplitude of the EOG as measured in the dark (dots) and during illumination (circles). Averages of measurements made on 20 subjects (dots, 0 to 30 min) 10 subjects (dots, 32 to 38 min) and 10 subjects (circles, 32 to 38 min). Vertical brackets show $2 \times$ standard deviation.

room on the amplitude of the EOG recorded after a period in darkness. The experiments were made at different times of day and the subjects came to the examination room from widely differing illumination conditions. A long preliminary period of dark-adaptation was therefore considered necessary. After this period (30 min) the standard illumination of the examination room was turned on and the increase in the amplitude of the EOG was tested in ten subjects whereas in another series of ten subjects employed as controls the dark-adaptation was continued. The standard illumination of the examination room consists of two series of three (60 cm 20 W) fluorescent tubes mounted uncovered in the ceiling. The matt grey ceiling has a relatively low capacity as a light diffuser whereas the walls of the room are white. The curtains were drawn over the windows. During the experiments the subjects to be examined were in a recumbent position facing two small fixation lights on the opposite

wall (30 degree angle between the fixation lights). During the period in the dark the subject was asked to keep his eyes closed. Conventional lead electrodes and a condenser-coupled differential amplifier connected to a pen were used for the recordings; the experimental conditions thus being identical to those used in this laboratory for routine ENG recordings.

Twenty women aged 20 to 25 were examined. The pupils were not dilated. The intensity of illumination used in these experiments was 130 lux as measured in front of the eyes with the photocell of a luxmeter placed perpendicularly to the direction of the eyes when looking at the fixation lights. The maximal luminance of the upper part of the opposite wall (above the fixation lights) was estimated to be 25 mLa corresponding to 1000 troland (4 mm average diameter of the pupil during illumination). The luminance of the opposite wall was not uniform and it should also be noted that the six fluorescent tubes placed in the ceiling were

Table 4 Mean amplitude (mm, 1 mm refers to 125 μ V), standard deviation and coefficient of variation of the EOG. The results refer to measurements performed on 92 subjects at the beginning of the experiment and after 8 minutes illumination with light of 10 000 troland intensity (following 15-minute period of dark-adaptation). Measurements made in the morning (8 a.m.) and in the evening (8 p.m.) have been combined.

	Mean amplitude	Standard deviation	Coefficient of variation
In the beginning of the experiment	5.31	1.65	0.309
After 8 minutes illumination	8.17	2.06	0.206

the amplitude of the EOG but also decreases the variation in the measurements of the amplitude.

This is further supported by results obtained in two additional series of experiments. In 22 subjects, each of them examined four times during the same day (8 a.m., 12 a.m., 4 p.m. and 8 p.m.) there was only moderate diurnal variation in the coefficient of variation whereas at each of the times of day examined the coefficient of variation was smaller after 8 minutes stimulation with light than at the beginning of the experiment or after dark-adaptation (Table 3). The differences are statistically significant, $p < 0.01$.

The coefficient of variation was also calculated for a greater number of subjects (92 subjects) examined both at 8 a.m. and 8 p.m., the results obtained in the morning and in the evening (as well as some of the results obtained in the 22 subjects described above) being now included in the same experimental group (184 observations). It is evident from these results (Table 4) that in the beginning of the experiment when the average amplitude of the EOG is 5.31 mm (660 μ V) the coefficient of variation is 0.309 whereas after 8 minutes illumination with light of 10 000 troland intensity the amplitude is increased to an average of 8.17 mm (1025 μ V) and the coefficient of variation is reduced to 0.252. The difference is statistically significant, $p < 0.01$.

4 Spontaneous variations in the amplitude of the electro-oculogram

It has been shown above that the amplitude of the EOG can be greatly increased, and the variation in the amplitude in constant conditions can be reduced by stimulation with light following dark-adaptation. Therefore, in the present study light-induced amplification of the response has been applied systematically to a large series of experiments concerned with spontaneous variations in the amplitude of the EOG. The results of these experiments are presented below.

The light used for stimulation was produced with a Leitz projector. Conventional lead electrodes and a condenser-coupled differential amplifier connected to a pen recorder were used, the experimental procedure being identical to

Table 5 Results of diurnal measurements (22 cases) of amplitude of the EOG (mm, 1 mm refers to 125 μ V). Four measurements were made in each case at four-hour intervals (as indicated). Each individual measurement is the mean of series of at least ten responses recorded. The means and standard deviations of the results obtained with 22 subjects are also shown. All measurements were made after an 8-minute period of illumination with light of 10 000 troland intensity following 15-minute period of dark-adaptation.

Fig. 5. Recordings of the EOG made with a condenser coupled differential amplifier connected to a pen recorder A, at the beginning of the experiment B after 15 minutes in the dark, C, after subsequent illumination with light of 10 000 troland intensity for 8 minutes, D after another 15-minute period of dark adaptation.

variation in the amplitude of the EOG occurred in the dark and during illumination with the standard lights of the routine ENG laboratory.

In the second part of this series of experiments a special light source, a Zeiss projector was used for stimulating the eyes with light. This light was projected on a white screen placed on the wall between the two fixation lights at a distance of 200 cm from the eyes of the subject. On this screen uniform illumination was produced over an area of 6400 cm² (80 × 80 cm square). The pupils were dilated the average pupil diameter during illumination being 7 mm. The intensity of illumination on the screen was 80 mLa which corresponds to 10 000 photopic troland. The experimental procedure was the same as described above but all experiments were now performed at 8 a.m. and measurements of the amplitude of the EOG were made only at the beginning of the experiment and after the following periods of time: 15 minutes in the dark, 8 minutes after the beginning of illumination and after a second period of dark-adaptation of 15 minutes duration.

The average results obtained in experiments performed on 36 subjects (women aged 20 to 25) are presented in Fig. 4 and original recordings of the EOG obtained in one case are shown in Fig. 5. It is evident from Fig. 4 that stimulation with light increased the amplitude of the

EOG on average by 45 per cent above the level measured at the beginning of the experiment. This illustration also shows that after a second 15-minute period of dark-adaptation the average amplitude is 32 per cent below the level measured after the first period of dark-adaptation.

It was of interest to know whether the variation in the measurements of the amplitude of the EOG could be reduced by increasing the amplitude by stimulation with light. Theoretically the damped oscillatory process of alteration in the amplitude should be "in phase" after stimulation with light following a constant period of dark-adaptation. Calculations based on the results already presented in Fig. 4 confirmed that this was the case. The coefficient of variation (SD/mean) calculated from results obtained 8 minutes after stimulation with light was 0.165 as compared with 0.266, 0.251 and 0.270 for the results obtained in the beginning of the experiment and after the first and second 15-minute periods of dark-adaptation respectively. This difference is statistically significant $p < 0.01$. Thus the low coefficient of variation 0.165 obtained after 8 minutes illumination with light of 10 000 troland intensity shows that stimulation with light not only increases

Table 3. Coefficient of variation of the amplitude of the EOG as calculated from results obtained with 22 healthy subjects at the beginning of the experiment and after the following successive periods: 15 minutes of dark-adaptation, 8 minutes of illumination with light of 10 000 troland intensity and 15 minutes of dark-adaptation. The results refer to experiments performed four times (as indicated) in the course of the same day.

	8 a.m.	12 a.m.	4 p.m.	8 p.m.
At the beginning of the experiment	0.223	0.193	0.186	0.165
After 15 minutes dark-adaptation	0.183	0.235	0.230	0.194
After 8 minutes illumination with light of 10 000 troland intensity	0.145	0.199	0.148	0.143
After second 15-minute period of dark-adaptation	0.228	0.232	0.233	0.202

Table 4 Mean amplitude (mm, 1 mm refers to 125 μ V), standard deviation and coefficient of variation of the EOG. The results refer to measurements performed on 92 subjects at the beginning of the experiment and after 8 minutes' illumination with light of 10 000 troland intensity (following 15 minute period of dark-adaptation). Measurements made in the morning (8 a.m.) and in the evening (8 p.m.) have been combined.

	Mean amplitude	Standard deviation	Coefficient of variation
In the beginning of the experiment	5.51	1.65	0.309
After 8 minutes' illumination	8.17	2.06	0.256

the amplitude of the EOG but also decreases the variation in the measurements of the amplitude.

This is further supported by results obtained in two additional series of experiments. In 22 subjects each of them examined four times during the same day (8 a.m. 12 a.m. 4 p.m. and 8 p.m.) there was only moderate diurnal variation in the coefficient of variation, whereas at each of the times of day examined the coefficient of variation was smaller after 8 minutes stimulation with light than at the beginning of the experiment or after dark-adaptation (Table 3). The differences are statistically significant, $p < 0.01$.

The coefficient of variation was also calculated for a greater number of subjects (92 subjects) examined both at 8 a.m. and 8 p.m. the results obtained in the morning and in the evening (as well as some of the results obtained in the 22 subjects described above) being now included in the same experimental group (184 observations). It is evident from these results (Table 4) that in the beginning of the experiment, when the average amplitude of the EOG is 5.51 mm (660 μ V) the coefficient of variation is 0.309 whereas after 8 minutes illumination with light of 10 000 troland intensity the amplitude is increased to an average of 8.17 mm (1025 μ V) and the coefficient of variation is reduced to 0.252. The difference is statistically significant, $p < 0.01$.

4 Spontaneous variations in the amplitude of the electro-oculogram

It has been shown above that the amplitude of the EOG can be greatly increased, and the variation in the amplitude in constant conditions can be reduced by stimulation with light following dark-adaptation. Therefore, in the present study light-induced amplification of the response has been applied systematically to a large series of experiments concerned with spontaneous variations in the amplitude of the EOG. The results of these experiments are presented below.

The light used for stimulation was produced with a "Leitz" projector. Conventional lead electrodes and a condenser-coupled differential amplifier connected to a pen recorder were used, the experimental procedure being identical to

Table 5 Results of diurnal measurements (22 cases) of amplitude of the EOG (mm, 1 mm refers to 125 μ V). Four measurements were made in each case at four-hour intervals (as indicated). Each individual measurement is the mean of a series of at least ten responses recorded. The means and standard deviations of the results obtained with 22 subjects are also shown. All measurements were made after an 8-minute period of illumination with light of 10 000 troland intensity following 15-minute period of dark-adaptation.

Fig. 6. Average amplitude (μV) of the EOG as measured in 22 subjects four times at four-hour intervals as indicated. Measurements were made at the beginning of the experiment (dots) and after the following periods: 15 minutes of preliminary dark-adaptation (dots), 8 minutes of illumination with light of 10 000 troland intensity (circles) and after a further 15-minute period of dark-adaptation (dots). Periods of darkness and illumination are marked on the abscissa with black and white respectively. Vertical bars indicate $2 \times$ standard deviation.

that used in this laboratory for routine ENG recordings. However, in a part of the study on diurnal variation in the amplitude a DC differential amplifier and chlorinated silver electrodes were used. The light projected on to a white screen (80×80 cm square) placed 2 metres in front of the subject who was asked to look rhythmically between the two fixation lights, the eyes thus making horizontal excursions of 30 degrees. The measurements made in individual cases refer to the average amplitude obtained in a series of at least ten recordings of the EOG.

The diurnal variation in the amplitude of the EOG was investigated in 22 women aged 20 to 25. Each subject was examined four times (at 4-hour intervals) during one day, the hours of examination being 8 a.m., 12 a.m., 4 p.m. and 8 p.m. Table 5 shows the average results ob-

tained after 8 minutes stimulation with light (10 000 troland, average diameter of the pupil 7 mm). It is evident that the average amplitude of the EOG decreases slightly in the course of the day. However, only the difference between the amplitude measured at 8 a.m. and 8 p.m. is statistically significant ($p < 0.001$), the average reduction in amplitude in this case being 13 per cent below the level measured in the morning. A statistically significant difference between the measurements made in the morning and in the evening was also found when measurements made after the first period in the dark ($p < 0.001$) or after the second period in the dark ($p < 0.01$) were used. It is also evident from Table 5 that it was only in twelve of the total of 22 subjects tested that the largest amplitude was found in the measurements made in the morning (8 a.m.). In seven cases the largest

Fig. 7 Diagram illustrating measurements made on 92 subjects of the diurnal change (increase +; decrease —) in the EOG potential level obtained after 15 minutes in the dark (ordinate: first dark trough) as related to the corresponding change in the light-induced fraction of this potential (abscissa: from the first dark trough to the light peak illumination for 8 minutes with light of 10 000 troland intensity). The results refer to measurements made at 8 a.m. and 8 p.m. The regression line calculated ($y = -0.426 - 0.293x$) indicates negative correlation (correlation coefficient -0.329).

amplitude was found at noon in three subjects in the afternoon (4 p.m.) but in no case in the evening (8 p.m.)

The means (μV) and standard deviations of these results are presented in Fig. 6. The results obtained in the beginning of the experiment as well as after a period in the dark after stimulation with light and after a second period of dark-adaptation are shown. It is evident from this illustration that not only the average maximum amplitude (circles) obtained after 8 minutes of stimulation with light but also the decreased amplitude after both the first and the second 15-minute period of dark-adaptation (dots) as well as the amplitude obtained in the beginning of the experiment (dots) all show

a slight continuous decrease during the course of the day. The ratio of the maximum amplitude (after illumination, circles) to the minimum amplitude (after subsequent dark-adaptation) multiplied by a hundred ($\frac{\text{light peak}}{\text{dark trough}} \times 100$) remains fairly constant: the values calculated from results obtained at 8 a.m., 12 a.m., 4 p.m. and 8 p.m. being 238, 232, 242 and 242 respectively. The corresponding ratios calculated on the basis of measurements made after the first 15-minute period in the dark (before illumination) are 161, 163, 177 and 181. These ratios show a continuous increase in the course of the day: the ratio obtained at 8 p.m. being 12.4 per cent larger than the ratio obtained at 8 a.m.

Fig. 6. Average amplitude (μV) of the EOG as measured in 22 subjects four times at four-hour intervals as indicated. Measurements were made at the beginning of the experiment (dots) and after the following periods: 15 minutes of preliminary dark-adaptation (dots), 8 minutes of illumination with light of 10 000 troland intensity (circles) and after a further 15-minute period of dark-adaptation (dots). Periods of darkness and illumination are marked on the abscissa with black and white respectively. Vertical bars indicate $2 \times$ standard deviation.

It is also evident from Table 5 that it was only in twelve of the total of 22 subjects tested that the largest amplitude was found in the measurements made in the morning (8 a.m.). In seven cases the largest

Fig. 2 Cumulative frequency histogram illustrating variation in the amplitude of the EOG as measured on two consecutive days. Abscissa, change in the amplitude as related to the amplitude measured 24 hours earlier (increase or decrease) in μV . Ordinate, percentage of measurements (total number of measurements = 278). All measurements were performed 8 minutes after the start of illumination with light of 1900 troland intensity.

cent (women) and 39 per cent (men) respectively. It is also evident that in some cases the amplitude increased, the largest increase observed in an individual case being 13 per cent (women) and 9 per cent (men) above the level measured in the morning respectively. However, the decrease in the amplitude observed in the data as a whole is statistically significant: t test value for women 9.4 $p < 0.001$ (at 38 degrees of freedom the t test value should be larger than 2.6 when $p < 0.001$) and correspondingly for men t test value 9.2 $p < 0.001$ (at 32 degrees of freedom the t test value should be larger than 2.7 when $p < 0.001$).

In a previous section of the present study it was shown that the velocity of the horizontal voluntary gaze movement does not show a

measurable diurnal variation. This fact rules out the possibility that the results described above could have been due to attenuation in the R-C network of the amplified signal as a result of slowing down in the evening of the rise time of the input signal (velocity of eye movement).

Moreover, it was observed in the course of measurements of the velocity of horizontal gaze movement made with a D.C. amplifier that the amplitude of the EOG was larger in the morning than in the evening. This result was obtained with all ten subjects examined. To complete this study similar measurements were made on twelve further subjects (5 women and 7 men, aged 20 to 25).

Chlorinated silver electrodes and a D.C. differential amplifier were used and the procedure

Accordingly it is evident from Fig 6 that the dots representing the measurements made after 15 minutes in the dark before illumination (first dark trough) show approximately the same slope as the circles (measurements made after 8 minutes of illumination light peak) whereas the dots representing measurements made after 15 minutes in the dark after illumination (second dark trough) show a much less sloping course. It is also evident from this illustration that the light induced increase in the amplitude of the EOG (from the first dark trough to the light peak) as expressed in absolute units (μV) remains fairly constant throughout the day. This is supported by some further results presented below and obtained with 92 subjects examined at both 8 a.m. and 8 p.m. These results show that the average increase in the amplitude obtained in the morning is 410 μV as compared with 407 μV in the evening. However further analysis of these results presented in Fig 7 indicates a negative correlation between the potential level measured before illumination (first dark trough) and the corresponding variation in the light induced fraction of the EOG. This correlation is statistically significant ($p < 0.01$). The regression line calculated for these measurements can be expressed by the function $y = -0.426 - 0.293x$ coefficient of correlation -0.329 .

As mentioned above a statistically significant diurnal change in the amplitude of the EOG was observed only when the measurements made in the morning (8 a.m.) were related to the measurements made in the evening (8 p.m.). Therefore additional measurements made on 70 subjects were performed only in the morning and in the evening (the completed results thus including measurements made on 92 subjects: 59 women and 33 men both aged 20 to 25). In 70 subjects the EOG was recorded at the beginning of the experiment after 15 minutes of dark-adaptation and after 8 minutes of illumination with light. It was observed in five female subjects that the amplitude was larger in the evening than in the morning whereas in

Table 6 Results (obtained with 59 women) showing diurnal variation in the amplitude of the EOG recorded with the aid of a condenser-coupled differential amplifier. The results show the relationship $\frac{A_1 - A_2}{A_1} \times 100$ (A_1 is the amplitude obtained at 8 a.m. and A_2 is the amplitude obtained at 8 p.m.). Measurements were made after 8 minutes stimulation with light of 10 000 troland intensity following a 15-minute period of dark adaptation.

the other females it decreased or was unaltered. An increase in the amplitude was also observed in two of the men whereas in the others the amplitude decreased or was unaltered. Mean values of the results (92 subjects) are presented in Table 6 (women) and Table 7 (men).

Tables 6 and 7 show the relationship $\frac{A_1 - A_2}{A_1}$ where A_1 is the amplitude obtained at 8 a.m. and A_2 the amplitude obtained at 8 p.m. Multiplied by one hundred this relationship shows the relative alteration in the amplitude: positive and negative results indicating a corresponding decrease or increase in the amplitude. It is evident from these results that there is a mean decrease in the amplitude of 13 per cent in women (Table 6) and 18 per cent in men (Table 7); the maximal decrease in amplitude observed in an individual case being 31 per

Table 7 Results (obtained with 33 men) showing diurnal variation in the amplitude of the EOG recorded with the aid of a condenser-coupled differential amplifier. The results show the relationship $\frac{A_1 - A_2}{A_1} \times 100$ (A_1 is the amplitude obtained 8 a.m. and A_2 is the amplitude obtained at 8 p.m.). cent (woman) and 39 per cent (man) respectively. It is also evident that in some cases the amplitude increased, the largest increase observed in an individual case being 13 per cent (woman) and 9 per cent (man) above the level measured in the morning respectively. However, the decrease in the amplitude observed in the data as a whole is statistically significant: t test value for women 9.4, $p < 0.001$ (at 38 degrees of freedom the t test value should be larger than 2.6 when $p < 0.001$) and correspondingly for men t test value 9.2, $p < 0.001$ (at 32 degrees of freedom the t test value should be larger than 2.7 when $p < 0.001$).

In a previous section of the present study it was shown that the velocity of the horizontal voluntary gaze movement does not show a

measurable diurnal variation. This fact rules out the possibility that the results described above could have been due to attenuation in the R-C network of the amplified signal as a result of slowing down in the evening of the rise time of the input signal (velocity of eye movement).

Moreover, it was observed in the course of measurements of the velocity of horizontal gaze movement made with a D.C. amplifier that the amplitude of the EOG was larger in the morning than in the evening. This result was obtained with all ten subjects examined. To complete this study similar measurements were made on twelve further subjects (5 women and 7 men, aged 20 to 25).

Chlorinated silver electrodes and a D.C. differential amplifier were used and the procedure

Fig. 9 Cumulative frequency histogram illustrating variation (increase or decrease) in the amplitude of the EOG as measured on two consecutive days. Abscissa: change in the amplitude as a percentage of the amplitude measured 24 hours earlier. Ordinate: percentage of measurements (total number of measurements = 278). All measurements were performed 8 minutes after the start of illumination with light of 1500 troland intensity.

was in general the same as already described (p. 13). However a somewhat slower velocity of the sweep (200 msec/cm) was used and automatic triggering was employed (in these subjects the velocity of the gaze movement was not measured).

Thus in a total of 22 subjects the amplitude of the EOG was measured (using D.C. amplification) both at 8 a.m. and 8 p.m. The recordings were made after 20 minutes of dark adaptation (no stimulation with light pupils not dilated). In 21 cases the smallest amplitude was found at 8 p.m. whereas in one case no alteration of the amplitude was observed. From the results obtained in the individual cases the relationship $\frac{A_1 - A_2}{A_1} \times 100$ (A_1 is the amplitude

of the EOG measured at 8 a.m. and A_2 the amplitude measured at 8 p.m.) was calculated. These results are given in Table 8. The average reduction in the amplitude of the EOG is as high as 19 per cent, the largest reduction in an individual case being 43 per cent below the amplitude measured in the morning. The t test

Table 8. Decrease in amplitude of the EOG within a period of twelve hours (between 8 a.m. and 8 p.m.) expressed as a percentage of the amplitude measured at 8 a.m. The measurements were made on 22 subjects, using D.C. amplification.

Fig. 10. Cumulative frequency histogram illustrating coefficient of variation of the change in the amplitude of the EOG. The results refer to measurements performed daily for a period of 4 successive days. For each of the total of 37 series of measurements performed on 19 subjects, the mean and standard deviation of the 24-hour change in amplitude were calculated. Abscissa, SD/mean of the change in amplitude. Ordinate, percentage of measurements (total number of measurements = 37). All measurements were performed 8 minutes after the start of illumination with light of 1900 troland intensity.

value 9.2 indicates that the reduction in the amplitude in these subjects is statistically significant ($p < 0.001$).

To investigate variation in the amplitude of the EOG in the course of a period longer than twelve hours 25 subjects (women, aged 20 to 25) were examined several times in the course of the month. To exclude diurnal variation in the amplitude re-examination of the same subject was always performed at the same time of day. An attempt was made to examine every subject on as many consecutive days as possible; however for practical reasons the examinations had to be restricted to periods of four or three successive days. Examinations were performed with 19 subjects in a total of 37 periods of four

days whereas on 6 subjects examinations were made in periods of three consecutive days only. Altogether 340 separate examinations were made. The EOG was recorded in the beginning of the experiment as well as after 15 minutes dark-adaptation and after 8 minutes stimulation with light of 1500 troland intensity (pupils not dilated). The results described below refer to the amplitude obtained after stimulation with light.

From this material it was possible to collect 278 separate cases in which the EOG was recorded on two consecutive days (24-hour interval between recordings). The results are presented in the form of a cumulative frequency histogram (Fig. 8). In this histogram the change

Fig 9 Cumulative frequency histogram illustrating variation (increase or decrease) in the amplitude of the EOG as measured on two consecutive days. Abcissa: change in the amplitude as a percentage of the amplitude measured 24 hours earlier. Ordinate: percentage of measurements (total number of measurements = 278). value 9.2 indicates that the reduction in the amplitude in these subjects is statistically significant ($p < 0.001$).

To investigate variation in the amplitude of the EOG in the course of a period longer than twelve hours, 25 subjects (women aged 20 to 25) were examined several times in the course of the month. To exclude diurnal variation in the amplitude re-examination of the same subject was always performed at the same time of day. An attempt was made to examine every subject on as many consecutive days as possible; however for practical reasons the examinations had to be restricted to periods of four or three successive days. Examinations were performed with 19 subjects in a total of 37 periods of four

days whereas on 6 subjects examinations were made in periods of three consecutive days only. Altogether 340 separate examinations were made. The EOG was recorded in the beginning of the experiment as well as after 15 minutes dark-adaptation and after 8 minutes stimulation with light of 1500 troland intensity (pupils not dilated). The results described below refer to the amplitude obtained after stimulation with light.

From this material it was possible to collect 278 separate cases in which the EOG was recorded on two consecutive days (24-hour interval between recordings). The results are presented in the form of a cumulative frequency histogram (Fig. 8). In this histogram the change

Fig. 11 Cumulative frequency histogram illustrating variation in the amplitude of the EOG as measured daily for a period of four successive days. Abscissa: difference between the largest and the smallest amplitude as a percentage of the smallest amplitude observed. Ordinate: percentage of measurements (total number of measurements = 37) (37 periods each 4 days, 19 subjects). All measurements were performed 8 minutes after the start of illumination with light of 1500 troland intensity.

(increase and decrease) in the amplitude in relation to the value measured 24 hours earlier (abscissa) is shown as a function of the percentage of measurements (total number of measurements = 278 ordinate). It is evident from this illustration that in 50 per cent of cases the change in the amplitude is less than 100 μV in 80 per cent of cases less than 200 μV and in 100 per cent of cases less than 500 μV . The same results are presented in Fig. 9 to show the change in amplitude (increase or decrease) as a percentage of the amplitude found 24 hours earlier. This histogram shows that in 60 per cent of cases the change in amplitude is less than 10 per cent and in most cases (more than 90 per cent) less than 20 per cent.

To investigate variation in the change of amplitude of the EOG recorded at 24-hour intervals the mean and standard deviation of the change in amplitude (increase or decrease within 24 hours) was calculated from results obtained with 19 subjects (37 periods of measurements performed on four successive days). The results are presented in the form of cumulative frequency histogram (Fig. 10) showing the coefficient of variation of the change in amplitude as a function of the percentage of measurements (total number of measurements = 37). It is evident from this illustration that in about 70 per cent of the cases (total 37) the coefficient of variation is larger than 0.5. In these cases the standard

Fig. 12. Cumulative frequency histogram illustrating variation in the amplitude of the EOG as measured on 25 subjects on several occasions for a period of one month (340 separate measurements). Abcissa, difference between the largest and the smallest amplitude as percentage of the smallest amplitude. Ordinate, percentage of measurements (total number of measurements = 25). All measurements were performed 8 minutes after the start of illumination with light of 1500 troland intensity.

deviation is larger than 50 per cent of the average change in the amplitude indicating a large variation in the change of the amplitude observed within 24 hours.

In the same set of experimental data consisting of 37 periods of measurements performed on four successive days the relationship $\frac{A_1 - A_2}{A_2} \times 100$ was calculated (A_1 is the largest amplitude and A_2 the smallest amplitude observed). The results are presented as a cumulative frequency histogram (Fig. 11). This histogram shows the difference between the largest and smallest amplitude (obtained within four days) expressed as a percentage of the smallest amplitude observed (abscissa) as a function of the

percentage of measurements (total number of measurements = 37 ordinate). It is evident from this illustration that in 10 per cent of cases the difference between the largest and the smallest amplitude is less than 10 per cent and in about 60 per cent of cases the difference is less than 20 per cent. In 11 per cent of cases the difference exceeds 35 per cent and only in one case is there a 50 per cent difference between the largest and the smallest amplitude obtained within a period of four successive days.

To investigate variation in the amplitude of the EOG in the course of one month the relationship $\frac{A_1 - A_2}{A_2} \times 100$ (where A_1 is the largest and A_2 the smallest amplitude obtained) was

Fig. 11 Cumulative frequency histogram illustrating variation in the amplitude of the EOG as measured daily for a period of four successive days. Abscissa, difference between the largest and the smallest amplitude as a percentage of the smallest amplitude observed. Ordinate, percentage of measurements (total number of measurements = 37) (37 periods each 4 days 19 subjects) All measurements were performed 8 minutes after the start of illumination with light of 1500 troland intensity

(increase and decrease) in the amplitude in relation to the value measured 24 hours earlier (abscissa) is shown as a function of the percentage of measurements (total number of measurements = 278 ordinate). It is evident from this illustration that in 50 per cent of cases the change in the amplitude is less than 100 μV in 80 per cent of cases less than 200 μV and in 100 per cent of cases less than 500 μV . The same results are presented in Fig. 9 to show the change in amplitude (increase or decrease) as a percentage of the amplitude found 24 hours earlier. This histogram shows that in 60 per cent of cases the change in amplitude is less than 10 per cent and in most cases (more than 90 per cent) less than 20 per cent.

To investigate variation in the change of amplitude of the EOG recorded at 24-hour intervals the mean and standard deviation of the change in amplitude (increase or decrease within 24 hours) was calculated from results obtained with 19 subjects (37 periods of measurements performed on four successive days). The results are presented in the form of cumulative frequency histogram (Fig. 10) showing the coefficient of variation of the change in amplitude as a function of the percentage of measurements (total number of measurements = 37). It is evident from this illustration that in about 70 per cent of the cases (total 37) the coefficient of variation is larger than 0.5. In these cases the standard

intervals for ten months was compared to the mean amplitudes obtained for these subjects for each of the ten separate months. The results are shown in Table 9. The *t* test values show

very little difference between the average results obtained in different months and the averaged results for the whole ten-month period.

From results obtained with 20 subjects the relationship $\frac{A_1 - A_2}{A_2} \times 100$ was calculated (A_1 is the largest amplitude and A_2 is the smallest). The results are presented in the form of a cumulative frequency histogram (Fig. 13). In this histogram the difference between the largest and the smallest amplitude observed within ten months is presented as a percentage of the smallest amplitude (abscissa) and is shown as a function of the percentage of measurements (total number of measurements = 20 ordinate). In all test subjects the difference between the largest and the smallest amplitude was greater than 20 per cent. In 80 per cent of cases the difference was less than 50 per cent and in 100 per cent of cases the difference was less than 70 per cent of the smallest amplitude.

Fig. 13 Cumulative frequency histogram illustrating variation in the amplitude of the EOG as measured on 20 subjects for a period of ten months (194 separate measurements). Abscissa: difference between the largest and the smallest amplitude as a percentage of the smallest amplitude. Ordinate: percentage of measurements (total number of measurements = 20). All measurements were performed 8 minutes after the beginning of illumination with light of 10 000 troland intensity.

calculated for the results obtained in all 25 subjects examined (340 separate measurements). The results are presented in the form of a cumulative frequency histogram (Fig. 12). The histogram shows the difference between the largest and smallest amplitudes (obtained within one month) expressed as a percentage of the smallest amplitude (abscissa) as a function of the percentage of measurements (total number of measurements = 25 ordinate). It is evident from this illustration that in all the subjects the difference between the largest and smallest amplitude is larger than 20 per cent. On the other hand in about 55 per cent of cases the difference is less than 30 per cent and in about 90 per cent of cases the difference between the

largest and smallest amplitudes is less than 50 per cent of the smallest amplitude.

The investigation of spontaneous variation in the amplitude of the EOG was completed with a study extending over ten months. These measurements were made on 20 women aged 20 to 25. However in the course of time the number fell and only 9 of these subjects attended all examinations. All experiments were performed at the same time of day (8 a.m.) and repeated at four weekly intervals. The recordings were made after 8 minutes of stimulation with light of 10 000 troland intensity (pupils dilated) following a 15-minute period of dark adaptation.

The mean amplitude for the nine subjects obtained from the EOGs performed at monthly

Table 9 Amplitude of the EOG (mm, 1 mm refers to 125 μ V) as measured on 9 subjects at four-weekly intervals during 10 months. Mean amplitude, standard deviation, maximum and minimum amplitudes, number of observations, as well as *t* test values for the different months are shown. All measurements were performed 8 minutes after stimulation with light of 10 000 troland intensity

V Discussion

It was confirmed in a series of preliminary experiments that small displacements of the two recording electrodes located on the skin near the temporal canthi of the lids of both eyes do not very much influence the recorded amplitude of the EOG. An average increase in the inter-electrode distance of more than 10 mm was required to decrease the amplitude of the EOG by an average of 10 per cent. In the present study markings made with ink on the skin greatly facilitated the positioning of the electrodes in cases where a second test was made within 24 hours. When the re-examination was made after a longer period of time the only way to check the location was to place the electrodes as near the temporal canthi of the lids as possible without causing excess of tear fluid at the skin electrode contact.

In another series of preliminary experiments it was observed that a lamp consisting of three fluorescent tubes mounted in the ceiling and used as part of the standard illumination of the routine ENG laboratory was strong enough to produce a considerable increase in the amplitude of the EOG previously measured in the dark adapted eye (Fig. 3). In most of the experiments of the present study however a standard light source was used to provide the illumination used for stimulation. The light was projected on a white screen in front of the subject to be examined and the average intensity of light was calculated to be 10 000 photopic troland (pupils dilated) and 1 500 photopic troland (pupils not dilated). The pupils were not dilated in cases where the experiments were repeated on several successive days because of the inconvenience to the test subject of prolonged mydriasis and paresis of accommodation. It should be noted that in the present experiments only a central part of the retina was directly

illuminated by the stimulating light the peripheral retina being illuminated by stray light. It is also known that the amplitude of the EOG measured after a constant period of illumination is linearly related to the logarithm of the intensity of the light used for stimulation (HECA and PAPST 1957). In the human eye an increase in the energy of the illumination above an average of 10 000 troland is not related to any further increase in amplitude (ARDEN and KELSEY 1962 b).

The results of the present work show that the increase in the amplitude provoked by the standard illumination (36 test subjects Fig. 3) is on the average 45 per cent above the level measured at the beginning of the experiment. This of course is sufficient to produce a considerable improvement in the signal-to-noise ratio of routine clinical recordings. Simultaneously with the increase in the amplitude the variation in the amplitude shows a statistically significant decrease: the coefficient of variation calculated from results obtained 8 minutes after stimulation with light being 0.165 as compared with 0.266, 0.251 and 0.270 for the results obtained at the beginning of the experiment and after the first and second 15 minute periods of dark-adaptation respectively. A larger number of data collected from experiments performed at different times of day (Table 4: 92 subjects, 184 measurements) shows that at the beginning of the experiment when the average amplitude of the EOG is 660 μ V the coefficient of variation is 0.309 whereas after 8 minutes of illumination with light of 10 000 troland intensity the amplitude is increased to an average of 1025 μ V and the coefficient of variation is reduced to 0.252. This result was statistically significant $p < 0.01$. It is also evident (Fig. 4) that the absolute value of the standard deviation

is smaller after illumination than at the beginning of the experiment and almost as large as after the first 15-minute period in the dark. In addition, it was established (Figs. 4 and 6) that after the second 15-minute period of dark adaptation the amplitude of the EOG is smaller than after the first period in the dark. This is in agreement with the results of ASERINSKY (1955) who found that when the eye was exposed to several periods of light and darkness the amplitude of the EOG was further reduced during every successive dark period until finally a constant level was reached. This is not apparent in the results of ARDEN and KELSEY (1962a).

To achieve a constant base-line value of the EOG response, a long period of steady illumination or darkness is required (KOLDEA, 1959). This fact complicates the results of the present study. A preliminary 15-minute period of dark adaptation is too short to achieve a constant base-line. After illumination, on the other hand, the minimum level of the dark trough has already been passed and the potential increases again if only a single measurement is made at the end of a 15-minute period in the dark. Moreover during the first 15-minute period in the dark at the beginning of the experiment it was observed that in individual cases the amplitude remained unaltered or showed a slight decrease or even an increase. Stimulation with light synchronizes the oscillations of the potential. The fact that the variation coefficient calculated for the amplitude obtained after the second period in the dark is as large as the coefficient obtained after the first period in the dark and larger than the coefficient obtained after an 8-minute period of illumination apparently indicates reduction in the accuracy of the measurements due to the strongly reduced amplitude of the response at the end of the second period in the dark. The constant 15-minute duration of the dark period used in the present study was originally chosen as a compromise between the favourable effects of a long period of dark-adaptation on the subsequent

light induced increase in the amplitude of the EOG (ARDEN and KELSEY 1962a) and the inconvenience to the test subject of an experiment of long total duration.

In the present work a statistically significant diurnal alteration in the amplitude of the EOG was observed both in the measurements made after a preliminary 15-minute period in the dark and after a period of light-adaptation of 8 minutes duration. The measurements made after the second 15-minute period in the dark showed much less alteration the diurnal variation in this case being statistically significant, $p < 0.01$. The results obtained after 8 minutes illumination showed that the average decrease in the amplitude of the EOG between 8 a.m. and 8 p.m. was 12.7 per cent (59 women Table 6) and 18.4 per cent (33 men, Table 7). In addition, it was confirmed in a series of experiments performed with a D.C. amplifier that the diurnal alteration in the amplitude of the EOG is not due to a diurnal variation in the velocity of the horizontal eye movements. It is also known that the velocity of a gaze movement cannot be altered by voluntary effort (BROCK NURST and LION 1951; MACKENZIE 1958). In agreement with the results described above these measurements (performed on 22 test subjects using D.C. amplification) showed that the amplitude measured at 8 p.m. was on the average 19.3 per cent smaller than the amplitude measured at 8 a.m. Slowing down of the velocity of the voluntary gaze movement may occur in physical and mental fatigue (DOGGE and CLINT, 1901; MILES 1929). KRIS (1960) found a remarkably low average velocity (100°/sec) of the horizontal eye movement in subjects examined early in the morning as compared with subjects examined in the afternoon (350°/sec). However only a totally reversed difference in the velocity of the eye movement (observed in the morning and in the afternoon) could be related to the largely increased amplitude of the EOG in the afternoon as observed by KRIS (1960).

The continuous slow reduction in the ampli-

V Discussion

It was confirmed in a series of preliminary experiments that small displacements of the two recording electrodes located on the skin near the temporal canthi of the lids of both eyes do not very much influence the recorded amplitude of the EOG. An average increase in the inter-electrode distance of more than 10 mm was required to decrease the amplitude of the EOG by an average of 10 per cent. In the present study markings made with ink on the skin greatly facilitated the positioning of the electrodes in cases where a second test was made within 24 hours. When the re-examination was made after a longer period of time the only way to check the location was to place the electrodes as near the temporal canthi of the lids as possible without causing excess of tear fluid at the skin electrode contact.

In another series of preliminary experiments it was observed that a lamp consisting of three fluorescent tubes mounted in the ceiling and used as part of the standard illumination of the routine ENG laboratory was strong enough to produce a considerable increase in the amplitude of the EOG previously measured in the dark adapted eye (Fig. 3). In most of the experiments of the present study however a standard light source was used to provide the illumination used for stimulation. The light was projected on a white screen in front of the subject to be examined and the average intensity of light was calculated to be 10 000 photopic troland (pupils dilated) and 1 500 photopic troland (pupils not dilated). The pupils were not dilated in cases where the experiments were repeated on several successive days because of the inconvenience to the test subject of prolonged mydriasis and paresis of accommodation. It should be noted that in the present experiments only a central part of the retina was directly

illuminated by the stimulating light the peripheral retina being illuminated by stray light. It is also known that the amplitude of the EOG measured after a constant period of illumination is linearly related to the logarithm of the intensity of the light used for stimulation (HECK and PARST 1957). In the human eye an increase in the energy of the illumination above an average of 10 000 troland is not related to any further increase in amplitude (ARDEN and KELSEY 1962 b).

The results of the present work show that the increase in the amplitude provoked by the standard illumination (36 test subjects Fig. 5) is on the average 45 per cent above the level measured at the beginning of the experiment. This of course is sufficient to produce a considerable improvement in the signal-to-noise ratio of routine clinical recordings. Simultaneously with the increase in the amplitude the variation in the amplitude shows a statistically significant decrease: the coefficient of variation calculated from results obtained 8 minutes after stimulation with light being 0.165 as compared with 0.266, 0.251 and 0.270 for the results obtained at the beginning of the experiment and after the first and second 15-minute periods of dark adaptation respectively. A larger number of data collected from experiments performed at different times of day (Table 4, 92 subjects, 184 measurements) shows that at the beginning of the experiment when the average amplitude of the EOG is 660 μ V the coefficient of variation is 0.309 whereas after 8 minutes of illumination with light of 10 000 troland intensity the amplitude is increased to an average of 1025 μ V and the coefficient of variation is reduced to 0.252. This result was statistically significant $p < 0.01$. It is also evident (Fig. 4) that the absolute value of the standard deviation

crease in the amplitude of the EOG probably being initiated in the receptors (see Introduction). The nature of the processes leading to diurnal variation in the activity of the pigment epithelium is not known. However in many other organs with great metabolic activity the circadian rhythm in the activity (MULLS 1966) parallels the slow diurnal variation in the blood level of the corticosteroid hormones (PETERSON 1957). In the human eye the effects of the corticosteroid hormones on intraocular pressure are well known.

In the present study spontaneous variations in the amplitude of the EOG were also investigated in the course of longer periods by making re-examinations at 24-hour intervals as well as at monthly intervals. In these experiments too stimulation with light was used to increase and stabilize the amplitude of the EOG and all experiments performed on the same test subject were made at the same time of day to avoid diurnal variation.

In 278 cases the amplitude of the EOG was measured on two consecutive days (24-hour interval between recordings). It was observed that in 60 per cent of cases the change in the amplitude (increase or decrease) was less than 10 per cent and in most cases (more than 90 per cent) it was less than 20 per cent (Fig. 9).

It was also of interest to know about the variation in the amplitude of the EOG recorded in the same subject on several consecutive days (24-hour interval between recordings). In 19 subjects such measurements were performed on four consecutive days (37 periods of measurements each of four day duration). It was found that the coefficient of variation (SD/mean) of the change in the amplitude (increase or decrease within 24 hours) was larger than 0.5 in about 70 per cent of cases indicating a great variation in the change of the amplitude within three successive 24-hour periods (Fig. 10). From the same experimental data obtained in 19 subjects (37 periods of measurements of four days duration) it was calculated that in 10 per cent of cases the difference between the

largest and the smallest amplitude was less than 10 per cent, and in about 60 per cent of cases it was less than 20 per cent. Only in a very few cases was there a difference of as much as 50 per cent between the largest and the smallest amplitude obtained within three consecutive 24-hour periods (Fig. 11). Apparently the relative difference between the largest and the smallest amplitude of the EOG increases with the length of the period between recordings. Measurements made on the same subject at monthly intervals showed (Fig. 12, 25 subjects, 340 measurements) that in this case this difference was larger than 20 per cent in all test subjects and in about 90 per cent of cases the difference was less than 50 per cent of the smallest amplitude. Only in nine test subjects could the measurements made at monthly intervals be continued for a period of ten months. But in this series of measurements also the difference between the smallest and the largest amplitude was greater than 20 per cent in all test subjects, whereas in 80 per cent of cases the difference was less than 50 per cent and in all cases the difference was less than 70 per cent of the smallest amplitude.

It can be concluded that substantial spontaneous variations occur in the amplitude of the EOG of healthy eyes. In most cases the amplitude shows a slow decrease from morning to night, whereas the changes observed over longer periods (24 hours, 4 days, 1 month and 10 months) show no regular pattern. Even after a month or ten months there were a few cases (10 to 20 per cent of the total number) in which the changes exceeded 50 per cent of the smallest amplitude observed, the change observed within 24 hours being of lesser magnitude. On the other hand, the changes observed within one month to ten months were in all cases larger than 20 per cent of the minimum amplitude. Day to day changes in the amplitude of the b-wave of the human ERG examined by SPIVEY and PEARLMAN (1963) in 19 young normal subjects varied from 16 to 95 per cent the difference between the largest and the

tude of the EOG observed in the present study is not likely to be related to a change in the skin-electrode resistance. Measurements performed on a large number of subjects (page 10) showed no difference in the average skin electrode resistance obtained in the morning and in the afternoon respectively. However the average age of these subjects was high as compared with the subjects of the main experiments of the present study. In two subjects (aged 22 and 26) RUTENFRANZ (1935) examined the diurnal variation of the electrical resistance of the skin on the palmar side of the wrist and found a maximum at 9 a.m. a minimum at 1 p.m. and another equally large maximum at 7 p.m. Apparently this type of variation in the electrical resistance of the skin is not synchronous with the continuous slow diurnal variation in the amplitude of the EOG described above. SNACKEL (1959) eroded the skin to reduce the electrical resistance at the site of the electrodes in their recordings of the human EOG. This procedure called "skin drilling" was not applied to the present study because of the complications caused to the skin as a result of experiments repeated at short intervals by using the same position of the electrodes.

The average results obtained in another group of 22 test subjects (Fig. 6) indicate that the light induced fraction of the amplitude of the EOG (the amplitude measured between the level obtained after a preliminary 15-minute period in the dark and the level obtained at the end of 11 minutes illumination) does not show diurnal variation and the average light induced fraction of the results obtained in 92 test subjects at 8 a.m. (410 μ V) equaled that obtained in the same subjects at 8 p.m. (407 μ V). However there are wide variations between individuals. The relationship between the diurnal alteration (8 a.m. to 8 p.m.) in the light-induced fraction of the EOG and the corresponding diurnal alteration in the amplitude measured at the end of the preliminary 15 minute period of dark adaptation (Fig. 7) shows that in most individual cases the amplitude

measured at the end of the preliminary period in the dark decreased in the course of the day whereas there was an almost equal number of cases showing an increase or a decrease in the light induced fraction of the EOG. This illustration also suggests that in cases with a large diurnal reduction in the amplitude as measured after 15 minutes in the dark the corresponding light induced fraction of the EOG is likely to show an increase. On the contrary in those cases with a small diurnal reduction in the amplitude level obtained at the end of the 15 minute period in the dark the corresponding light induced fraction of the EOG is likely to remain unaltered or to show a diurnal decrease. This is expressed by the negative correlation between these two processes illustrated in Fig. 7 by the interrupted line.

ASERINSKY (1935) when studying the effects of sleep on the amplitude of the EOG found that the amplitude measured early in the morning was larger than the amplitude measured in the same subjects the previous evening. This is in apparent agreement with the slow reduction in the amplitude of the EOG during the course of the day observed in most subjects examined in the present study. The amplitude was only found to increase in a minority of cases and in these cases the increase was small as compared with that (doubled or trebled amplitude) described by LARIS (1960). The slow decrease in the amplitude of the EOG in the course of the day resembles the diurnal variation in the amplitude of the b-wave of the human electroretinogram (ERG) described by ROYCE and ERCOLES (1967). On the other hand in the monkey eye there seems to be a simple linear relationship between the amplitude of the EOG and the amplitude of the ERG (GOURAS and CARR 1964). In the human eye and in the eye of the rabbit SPIVEY and PLARLIAN (1963) have observed considerably day to day variations in the amplitude of ERG.

The EOG is known to provide an indirect record of the activity of the pigment epithelium of the retina the light induced process (in

crease in the amplitude of the EOG probably being initiated in the receptors (see Introduction). The nature of the processes leading to diurnal variation in the activity of the pigment epithelium is not known. However in many other organs with great metabolic activity the circadian rhythm in the activity (MILLS, 1966) parallels the slow diurnal variation in the blood level of the corticosteroid hormones (PETTERSON 1957). In the human eye the effects of the corticosteroid hormones on intraocular pressure are well known.

In the present study spontaneous variations in the amplitude of the EOG were also investigated in the course of longer periods by making re-examinations at 24-hour intervals, as well as at monthly intervals. In these experiments too stimulation with light was used to increase and stabilize the amplitude of the EOG and all experiments performed on the same test subject were made at the same time of day to avoid diurnal variation.

In 278 cases the amplitude of the EOG was measured on two consecutive days (24-hour interval between recordings). It was observed that in 60 per cent of cases the change in the amplitude (increase or decrease) was less than 10 per cent and in most cases (more than 90 per cent) it was less than 20 per cent (Fig. 9).

It was also of interest to know about the variation in the amplitude of the EOG recorded in the same subject on several consecutive days (24-hour interval between recordings). In 19 subjects such measurements were performed on four consecutive days (37 periods of measurements each of four day duration). It was found that the coefficient of variation (SD/mean) of the change in the amplitude (increase or decrease within 24 hours) was larger than 0.5 in about 70 per cent of cases, indicating a great variation in the change of the amplitude within three successive 24-hour periods (Fig. 10). From the same experimental data obtained in 19 subjects (37 periods of measurements of four days duration) it was calculated that in 10 per cent of cases the difference between the

largest and the smallest amplitude was less than 10 per cent and in about 60 per cent of cases it was less than 20 per cent. Only in a very few cases was there a difference of as much as 50 per cent between the largest and the smallest amplitude obtained within three consecutive 24-hour periods (Fig. 11). Apparently the relative difference between the largest and the smallest amplitude of the EOG increases with the length of the period between recordings. Measurements made on the same subject at monthly intervals showed (Fig. 12, 25 subjects, 340 measurements) that in this case this difference was larger than 20 per cent in all test subjects, and in about 90 per cent of cases the difference was less than 50 per cent of the smallest amplitude. Only in nine test subjects could the measurements made at monthly intervals be continued for a period of ten months. But in this series of measurements also the difference between the smallest and the largest amplitude was greater than 20 per cent in all test subjects whereas in 80 per cent of cases the difference was less than 50 per cent and in all cases the difference was less than 70 per cent of the smallest amplitude.

It can be concluded that substantial spontaneous variations occur in the amplitude of the EOG of healthy eyes. In most cases the amplitude shows a slow decrease from morning to night, whereas the changes observed over longer periods (24 hours, 4 days, 1 month and 10 months) show no regular pattern. Even after a month or ten months there were a few cases (10 to 20 per cent of the total number) in which the changes exceeded 50 per cent of the smallest amplitude observed the change observed within 24 hours being of lesser magnitude. On the other hand, the changes observed within one month to ten months were in all cases larger than 20 per cent of the minimum amplitude. Day to day changes in the amplitude of the b-wave of the human ERG examined by SPIVEY and FRANKMAN (1963) in 19 young normal subjects varied from 16 to 95 per cent the difference between the largest and the

tude of the EOG observed in the present study is not likely to be related to a change in the skin-electrode resistance. Measurements performed on a large number of subjects (page 10) showed no difference in the average skin electrode resistance obtained in the morning and in the afternoon respectively. However the average age of these subjects was high as compared with the subjects of the main experiments of the present study. In two subjects (aged 22 and 26) RUTENFRANZ (1955) examined the diurnal variation of the electrical resistance of the skin on the palmar side of the wrist and found a maximum at 9 a.m., a minimum at 1 p.m. and another equally large maximum at 7 p.m. Apparently this type of variation in the electrical resistance of the skin is not synchronous with the continuous slow diurnal variation in the amplitude of the EOG described above. SHACKEL (1959) eroded the skin to reduce the electrical resistance at the site of the electrodes in their recordings of the human EOG. This procedure called "skin drilling" was not applied to the present study because of the complications caused to the skin as a result of experiments repeated at short intervals by using the same position of the electrodes.

The average results obtained in another group of 22 test subjects (Fig. 6) indicate that the light induced fraction of the amplitude of the EOG (the amplitude measured between the level obtained after a preliminary 15 minute period in the dark and the level obtained at the end of 8 minutes illumination) does not show diurnal variation and the average light induced fraction of the results obtained in 92 test subjects at 8 a.m. (410 μ V) equaled that obtained in the same subjects at 8 p.m. (407 μ V). However there are wide variations between individuals. The relationship between the diurnal alteration (8 a.m. to 8 p.m.) in the light induced fraction of the EOG and the corresponding diurnal alteration in the amplitude measured at the end of the preliminary 15 minute period of dark-adaptation (Fig. 7) shows that in most individual cases the amplitude

measured at the end of the preliminary period in the dark decreased in the course of the day, whereas there was an almost equal number of cases showing an increase or a decrease in the light induced fraction of the EOG. This illustration also suggests that in cases with a large diurnal reduction in the amplitude as measured after 15 minutes in the dark the corresponding light induced fraction of the EOG is likely to show an increase. On the contrary in those cases with a small diurnal reduction in the amplitude level obtained at the end of the 15-minute period in the dark the corresponding light induced fraction of the EOG is likely to remain unaltered or to show a diurnal decrease. This is expressed by the negative correlation between these two processes illustrated in Fig. 7 by the interrupted line.

ASERINSKY (1955) when studying the effects of sleep on the amplitude of the EOG found that the amplitude measured early in the morning was larger than the amplitude measured in the same subjects the previous evening. This is in apparent agreement with the slow reduction in the amplitude of the EOG during the course of the day observed in most subjects examined in the present study. The amplitude was only found to increase in a minority of cases and in these cases the increase was small as compared with that (doubled or trebled amplitude) described by ARIS (1960). The slow decrease in the amplitude of the EOG in the course of the day resembles the diurnal variation in the amplitude of the b-wave of the human electroretinogram (ERG) described by RONCHI and ERCOLIS (1967). On the other hand in the monkey eye there seems to be a simple linear relationship between the amplitude of the EOG and the amplitude of the ERG (GOUKAS and CARR 1964). In the human eye and in the eye of the rabbit SPIVEY and PEARLMAN (1963) have observed considerably day to day variations in the amplitude of ERG.

The EOG is known to provide an indirect record of the activity of the pigment epithelium of the retina, the light induced process of in-

crease in the amplitude of the EOG probably being initiated in the receptors (see Introduction). The nature of the processes leading to diurnal variation in the activity of the pigment epithelium is not known. However in many other organs with great metabolic activity the circadian rhythm in the activity (MILLS, 1966) parallels the slow diurnal variation in the blood level of the corticosteroid hormones (PETERSON 1957). In the human eye the effects of the corticosteroid hormones on intraocular pressure are well known.

In the present study spontaneous variations in the amplitude of the EOG were also investigated in the course of longer periods by making re-examinations at 24-hour intervals as well as at monthly intervals. In these experiments, too, stimulation with light was used to increase and stabilize the amplitude of the EOG and all experiments performed on the same test subject were made at the same time of day to avoid diurnal variation.

In 278 cases the amplitude of the EOG was measured on two consecutive days (24-hour interval between recordings). It was observed that in 60 per cent of cases the change in the amplitude (increase or decrease) was less than 10 per cent and in most cases (more than 90 per cent) it was less than 20 per cent (Fig. 9).

It was also of interest to know about the variation in the amplitude of the EOG recorded in the same subject on several consecutive days (24-hour interval between recordings). In 19 subjects such measurements were performed on four consecutive days (37 periods of measurements each of four day duration). It was found that the coefficient of variation (SD/mean) of the change in the amplitude (increase or decrease within 24 hours) was larger than 0.5 in about 70 per cent of cases indicating a great variation in the change of the amplitude within three successive 24-hour periods (Fig. 10). From the same experimental data obtained in 19 subjects (37 periods of measurements of four days duration) it was calculated that in 10 per cent of cases the difference between the

largest and the smallest amplitude was less than 10 per cent, and in about 60 per cent of cases it was less than 20 per cent. Only in a very few cases was there a difference of as much as 50 per cent between the largest and the smallest amplitude obtained within three consecutive 24-hour periods (Fig. 11). Apparently the relative difference between the largest and the smallest amplitude of the EOG increases with the length of the period between recordings. Measurements made on the same subject at monthly intervals showed (Fig. 12, 25 subjects 340 measurements) that in this case this difference was larger than 20 per cent in all test subjects and in about 90 per cent of cases the difference was less than 50 per cent of the smallest amplitude. Only in nine test subjects could the measurements made at monthly intervals be continued for a period of ten months. But in this series of measurements also the difference between the smallest and the largest amplitude was greater than 20 per cent in all test subjects whereas in 80 per cent of cases the difference was less than 50 per cent and in all cases the difference was less than 70 per cent of the smallest amplitude.

It can be concluded that substantial spontaneous variations occur in the amplitude of the EOG of healthy eyes. In most cases the amplitude shows a slow decrease from morning to night whereas the changes observed over longer periods (24 hours, 4 days, 1 month and 10 months) show no regular pattern. Even after a month or ten months there were a few cases (10 to 70 per cent of the total number) in which the changes exceeded 50 per cent of the smallest amplitude observed, the change observed within 24 hours being of lesser magnitude. On the other hand the changes observed within one month to ten months were in all cases larger than 20 per cent of the minimum amplitude. Day to day changes in the amplitude of the b-wave of the human ERG examined by SPIVEY and PEARLMAN (1963) in 19 young normal subjects varied from 16 to 95 per cent the difference between the largest and the

smallest amplitude being expressed in per cent of the smallest. Excluding three extreme cases this variation was from 16 to 45 per cent. In the present study the change in the amplitude of the EOG obtained within 24 hours was expressed in per cent of the first measurement (made 24 hours earlier) this change being less than 10 per cent in 60 per cent of cases and less than 20 per cent in 90 per cent of cases. These results are not directly comparable with earlier reports. The results of DAVIS and SHACKEL (1960) are presented in absolute units (μV) only moreover there are fundamental differences in the recording procedures. They found that in twelve healthy young subjects the average change in the amplitude was 76 μV within 24 hours (30 degree excursion of the eyes) this change being larger than 200 μV in 6 per cent of cases and larger than 100 μV in 25 per cent of cases. Correspondingly in the present study the change in the amplitude was larger than 200 μV in 20 per cent of cases and larger than 100 μV in 50 per cent of cases. In the results of DAVIS and SHACKEL (1960) the time between the recordings (1 hour 24 hours 8 weeks) did not alter the results very much and there was no definite diurnal pattern of variation.

The clinical evaluation of the intensity of spontaneous nystagmus is based on measurements of the maximal velocity of the slow phase of the nystagmus. Accordingly the velocity of the slow phase of the nystagmus observed during the maximal intensity of the caloric nystagmus is the best indicator of the caloric excitability of the labyrinthine organ. On the other hand the total (summed) amplitude of the nystagmus observed during the caloric reaction provides a reliable indicator of the excita-

bility (ASCHAN, BERGSTEDT and STABLE, 1956; HENRIKSSON 1956). In the clinical procedure of recording the nystagmus the subject is occasionally asked to close his eyes or to keep them open. Thus the fact that light and darkness alter the amplitude of the corneo-fundal potential indicates the necessity of measuring the illumination in the ENG laboratory. Moreover it is important to make frequent calibrations of the amplitude by asking the subject to perform horizontal gaze movements through a constant angle. The favourable effect of a long period of preliminary dark-adaptation for the clinical ENG recording has already been emphasized by MUNTJE FOG (1963). On the other hand, as mentioned above it is difficult to achieve a steady base-line level (KOLDER 1959). Even short periods of light start the slow oscillatory alteration in the amplitude of the corneo-fundal potential (ARDEN and HELSEY 1962a). However to obtain a maximum increase in the amplitude it is necessary to use a longer period of continuous illumination following a constant period in the dark and to perform the recordings 8 to 10 minutes after the beginning of the illumination. This procedure not only facilitates the detection of nystagmus of limited amplitude (ELENIUS and AANTAA 1967) but also markedly improves the signal-to-noise ratio of the recordings. In the present work the use of a light induced increase in the amplitude of the corneo-fundal potential made it possible to use relatively low amplification (1250 $\mu V/cm$) and the quality of the recordings was good. The use of higher amplification in the present study was limited by the restricted maximal vertical excursion (20 mm) of the pen recorder of the electro-nystagmograph used.

Summary

When recording the electro-oculogram (EOG) with the aid of a condenser-coupled differential amplifier and two electrodes placed on the skin near the temporal canthi of the lids of both eyes, it was found, that a lateral displacement of one or both electrodes reduced the amplitude of the EOG an increase in the inter-electrode distance of 10 mm corresponding to a 10 per cent average reduction in the amplitude. In the original (primary) position the nearest edge of the electrodes was 14 mm from the canthos of the lids. The EOG was evoked by moving the eyes horizontally from one fixation light to the other (through a constant angle).

The effect of illumination on the amplitude of the EOG was first investigated after 30 minutes of dark-adaptation by switching on the standard illumination (1000 troland) of the examination room. This light increased the amplitude in 8 minutes (20 subjects) on the average by 39 per cent above the level obtained at the beginning of the experiment.

The effect of stronger illumination (10 000 troland) was investigated with the aid of a Zeiss projector by switching on the light after 15 minutes of dark-adaptation. It was found that in 8 minutes this light increased the amplitude by an average (36 subjects) of 45 per cent above the level obtained at the beginning of the experiment. It was also found that the variation in the amplitude was smaller after 8 minutes of illumination (large amplitude) than at the beginning of the experiment.

The diurnal variation in the amplitude of the EOG was investigated by performing the experiments after 8 minutes of light-adaptation (10 000 troland) following a 15-minute period of dark-adaptation. Measurements were performed at 8 a.m., 12 a.m., 4 p.m., and 8 p.m. A slow diurnal reduction between 8 a.m. and

8 p.m. was found, the difference between the values being statistically significant ($p < 0.001$). The magnitude of the reduction was on the average 12.7 per cent (59 women) and 18.4 per cent (33 men).

Diurnal variation in the amplitude of the EOG was also found in control experiments made using a D.C. differential amplifier the corresponding average reduction in the amplitude in this series of experiments (22 subjects) being 19.3 per cent. In addition, it was found (by using D.C. amplification) that the velocity of the voluntary horizontal gaze movement does not show diurnal variation.

The average light induced fraction of the EOG (measured from the level obtained after 15 minutes in the dark before illumination to the level obtained 8 minutes after the beginning of illumination) was found to be the same (92 subjects) at 8 a.m. as at 8 p.m. Individual cases however showed a slight negative correlation (coefficient of correlation -0.329) between the amplitude obtained after 15 minutes in the dark and the light-induced fraction of the EOG.

In 278 cases the amplitude of the EOG was measured on two consecutive days (24-hour interval between recordings). It was observed that in 60 per cent of these cases the change in the amplitude (increase or decrease) was less than 10 per cent and in most cases (more than 90 per cent) it was less than 20 per cent.

In 19 subjects (37 periods of measurements each of four days duration) it was calculated that in 10 per cent of cases the difference between the largest and the smallest amplitude was less than 10 per cent and in about 60 per cent of cases it was less than 20 per cent. Only in a very few cases was there a difference of as much as 30 per cent between the largest

smallest amplitude being expressed in per cent of the smallest. Excluding three extreme cases this variation was from 16 to 45 per cent. In the present study the change in the amplitude of the EOG obtained within 24 hours was expressed in per cent of the first measurement (made 24 hours earlier) this change being less than 10 per cent in 60 per cent of cases and less than 20 per cent in 90 per cent of cases. These results are not directly comparable with earlier reports. The results of DAVIS and SHACKEL (1960) are presented in absolute units (μV) only moreover there are fundamental differences in the recording procedures. They found that in twelve healthy young subjects the average change in the amplitude was 76 μV within 24 hours (30 degree excursion of the eyes) this change being larger than 200 μV in 6 per cent of cases and larger than 100 μV in 25 per cent of cases. Correspondingly in the present study the change in the amplitude was larger than 200 μV in 20 per cent of cases and larger than 100 μV in 50 per cent of cases. In the results of DAVIS and SHACKEL (1960) the time between the recordings (1 hour 24 hours 8 weeks) did not alter the results very much and there was no definite diurnal pattern of variation.

The clinical evaluation of the intensity of spontaneous nystagmus is based on measurements of the maximal velocity of the slow phase of the nystagmus. Accordingly the velocity of the slow phase of the nystagmus observed during the maximal intensity of the caloric nystagmus is the best indicator of the caloric excitability of the labyrinthine organ. On the other hand the total (summed) amplitude of the nystagmus observed during the caloric reaction provides a reliable indicator of the excita-

bility (ASCHAN, BERGSTEDT and STAHL 1956; HENRIKSSON 1956). In the clinical procedures of recording the nystagmus, the subject is occasionally asked to close his eyes or to keep them open. Thus the fact that light and darkness alter the amplitude of the corneo-fundal potential indicates the necessity of measuring the illumination in the ENG laboratory. Moreover it is important to make frequent calibrations of the amplitude by asking the subject to perform horizontal gaze movements through a constant angle. The favourable effect of a long period of preliminary dark adaptation for the clinical ENG recording has already been emphasized by MUNTZ and FOG (1963). On the other hand as mentioned above it is difficult to achieve a steady base-line level (KOLDER 1959). Even short periods of light start the slow oscillatory alteration in the amplitude of the corneo-fundal potential (ARDEN and KELSEY 1962a). However to obtain a maximum increase in the amplitude it is necessary to use a longer period of continuous illumination following a constant period in the dark, and to perform the recordings 8 to 10 minutes after the beginning of the illumination. This procedure not only facilitates the detection of nystagmus of limited amplitude (ELENIUS and AANTAA 1967) but also markedly improves the signal-to-noise ratio of the recordings. In the present work the use of a light induced increase in the amplitude of the corneo-fundal potential made it possible to use relatively low amplification (1250 $\mu V/cm$) and the quality of the recordings was good. The use of higher amplification in the present study was limited by the restricted maximal vertical excursion (20 mm) of the pen recorder of the electro-nystagmograph used.

Summary

When recording the electro-oculogram (EOG) with the aid of a condenser-coupled differential amplifier and two electrodes placed on the skin near the temporal canthi of the lids of both eyes, it was found, that a lateral displacement of one or both electrodes reduced the amplitude of the EOG an increase in the inter-electrode distance of 10 mm corresponding to a 10 per cent average reduction in the amplitude. In the original (primary) position the nearest edge of the electrodes was 14 mm from the canthos of the lids. The EOG was evoked by moving the eyes horizontally from one fixation light to the other (through a constant angle)

The effect of illumination on the amplitude of the EOG was first investigated after 30 minutes of dark-adaptation by switching on the standard illumination (1000 troland) of the examination room. This light increased the amplitude in 8 minutes (20 subjects) on the average by 39 per cent above the level obtained at the beginning of the experiment

The effect of stronger illumination (10 000 troland) was investigated with the aid of a Zeiss projector by switching on the light after 15 minutes of dark-adaptation. It was found that in 8 minutes this light increased the amplitude by an average (36 subjects) of 43 per cent above the level obtained at the beginning of the experiment. It was also found that the variation in the amplitude was smaller after 8 minutes of illumination (large amplitude) than at the beginning of the experiment.

The diurnal variation in the amplitude of the EOG was investigated by performing the experiments after 8 minutes of light-adaptation (10 000 troland) following a 15-minute period of dark-adaptation. Measurements were performed at 8 a.m., 12 a.m., 4 p.m. and 8 p.m. A slow diurnal reduction between 8 a.m. and

8 p.m. was found, the difference between the values being statistically significant ($p < 0.001$). The magnitude of the reduction was on the average 12.7 per cent (59 women) and 18.4 per cent (33 men)

Diurnal variation in the amplitude of the EOG was also found in control experiments made using a D.C. differential amplifier the corresponding average reduction in the amplitude in this series of experiments (22 subjects) being 19.3 per cent. In addition, it was found (by using D.C. amplification) that the velocity of the voluntary horizontal gaze movement does not show diurnal variation.

The average light-induced fraction of the EOG (measured from the level obtained after 15 minutes in the dark before illumination to the level obtained 8 minutes after the beginning of illumination) was found to be the same (92 subjects) at 8 a.m. as at 8 p.m. Individual cases, however, showed a slight negative correlation (coefficient of correlation -0.329) between the amplitude obtained after 15 minutes in the dark and the light-induced fraction of the EOG

In 278 cases the amplitude of the EOG was measured on two consecutive days (24-hour interval between recordings). It was observed that in 60 per cent of these cases the change in the amplitude (increase or decrease) was less than 10 per cent and in most cases (more than 90 per cent) it was less than 20 per cent

In 19 subjects (37 periods of measurements each of four days duration) it was calculated that in 10 per cent of cases the difference between the largest and the smallest amplitude was less than 10 per cent, and in about 60 per cent of cases it was less than 20 per cent. Only in a very few cases was there a difference of as much as 50 per cent between the largest

and the smallest amplitude obtained within three consecutive 24 hour periods.

Measurements repeated at monthly intervals showed (25 subjects 340 measurements) that in this case this difference was greater than 20 per cent in all test subjects and in about 90 per cent of cases the difference was less than 50 per cent of the smallest amplitude. Only in nine test subjects could measurements made at monthly intervals be extended over a period of ten months. In this series of measurements the difference between the smallest and largest amplitude was likewise greater than 20 per cent in all test subjects whereas in 80 per cent of cases the difference was less than 50 per cent and in all cases less than 70 per cent of the smallest amplitude.

The fact that light and darkness alter the amplitude of the corneo-fundal potential indicates the necessity of measuring the illumination in the ENG laboratory. It is also necessary to make frequent calibrations of the amplitude by asking the subject to perform horizontal eye movements through a constant angle. Similar calibrations can be used to measure the slow spontaneous alterations in the amplitude. On the other hand light induced amplification of the potential can be used to improve the signal-to-noise ratio of the recordings. This may facilitate the detection of nystagmus of limited amplitude.

Acknowledgements

I am grateful to my teacher in oto-laryngology Professor Otto H. Neuman, M.D. for his continuing interest in the progress of this investigation and for placing at my disposal all facilities of the ENG laboratory.

The theme of this study was suggested to me by Dr Valter Elenius M.D. whose guidance and instructions have been invaluable. He also allowed me to use in a part of this study a Tektronix oscilloscope presented to him by the Sigrid Juselius Foundation. I also wish to thank Mr Pekka Aho M.Sc. for statistical treatment

of part of the data, Dr Heikki Lang M.D. for kindly helping me to measure the resistance of the electrodes Mrs. Leila Rinne for her assistance in examination of the patients Mrs. Jean Margaret Perttunen, B.Sc., for checking the English language and Mrs. Maija Lövgren for typing the manuscript.

A fellowship from the Council of Europe made it possible for me to visit the neuro-otological laboratories at the Universities of Aarhus Copenhagen Lund and Uppsala.

and the smallest amplitude obtained within three consecutive 24 hour periods

Review of the literature

The various opinions encountered in the literature as to a possible relationship between adenoids on the one hand and on the other special facial expressions, types of dentition and mouth breathing can be grouped as follows

1 The combination of adenoids and mouth breathing gives rise to a special facial expression and type of dentition

2 The combination of adenoids and mouth breathing does not affect the facial expression and type of dentition

3 Adenoids lead to mouth breathing in cases with particular facial characteristics and types of dentition

1 The combination of adenoids and mouth breathing gives rise to a special facial expression and type of dentition

The blocking of the nasopharynx by adenoids with the diminution or cessation of nasal breathing has been presented as a mechanism to explain the alteration of normal growth and development of the jaws. The assumption is that the absence of nasal breathing may in directly affect the form of the maxillary arch through interference with the growth of the upper facial skeleton as a whole and with the floor of the nasal cavities in particular.

Once attention had been drawn by Meyer (1868) to the deleterious effect of adenoids on the hearing as well as on the general condition of a growing child, only a few years passed before Tomes (1872) reported that children who are mouth breathers on account of large adenoids usually display contracted, V shaped dental arches. This form of jaw has been attributed to the circumstance that mouth breathers keep the lips parted and the tongue

low the theory being that imbalance between pressure from the tongue and the cheek muscles results in the alveolar process in the premolar region being pressed medially by the cheek muscles at the same time as the anterior part of the upper jaw is pressed forwards. This line of reasoning has been termed the *compression theory* (Nordlund 1918). Many other authors, e.g. Angle (1907), Kärbitz (1910), Izard (1925), Bowen & Balyeat (1934), Neivert (1939), Cooke (1940), McCoy (1941), Henley (1944), Massler, Poncher & Schour (1945), Subtelny (1954), Negus (1955), Duyzing (1963) and Moyers (1963) appear to be of much the same opinion when they maintain that the direct cause of the deformation of the alveolar process in mouth breathers, partly as a consequence of adenoids, lies in the atypical movements of the tongue or other facial muscles that are usually associated with mouth breathing.

Körner (1891) and Bentzen (1903) have suggested that mouth breathing in association with adenoids, besides leading to narrow dental arches, may also give rise to compression of the upper jaw. According to this view the height of the palatal vault increases to the same extent as the nasal cavity becomes atrophied as a result of inactivity. This has been termed the *inaction theory* (Nordlund, 1918).

Bloch (1903) and Michel (1908) believed that the high palate which develops when there is an impediment to nasal breathing is a result of the upward direction of the air stream which impinges on the palate in mouth breathing. This has been termed the *excavation theory* (Nordlund 1918).

Kantorowicz (1916) and Wustrow (1917) have expressed the view that the high palate

in cases with mouth breathing and nasal obstruction is due to the raised negative air pressure in the nasal cavity and the resulting increased difference between the pressure in the mouth and nasal cavity.

Joshi (1964) found in 387 children that oronasal breathers, in association with enlarged tonsils and adenoids, are far more likely to develop Angle class II, 1 than nasal breathers.

Ricketts (1968) reporting that adenoid children displayed definite characteristics in facial expression and type of dentition, termed these observations "the respiratory obstruction syndrome". Characteristic findings in these children, who are mouth breathers, are considered to be protrusion of the tongue between the upper and lower incisors in swallowing, the occurrence of open bite, uni- or bi-lateral crossbite and the head tilted backwards somewhat. Furthermore unilateral crossbite is reported to have corrected spontaneously in three patients after adenoidectomy.

2. The combination of adenoids and mouth breathing does not affect the facial expression and type of dentition

Several authors have reported that so-called adenoid faces is not always associated with adenoids and mouth breathing, and that a particular type of dentition is not always found in mouth breathers with or without adenoids.

As early as 1888 Kingsley stated that he could not accept the view that muscular contraction of the cheeks could produce a contraction of the palate. He felt that the V-shaped palate was inherited and not acquired through mouth breathing.

In connection with extensive facial measurements, Siebenmann (1897) found that adenoids commonly occur in leptoprosopic individuals but were not therefore etiological responsible for this form of face.

McKenzie (1909) investigated 22 children with adenoids and found that over 40% had normal palates and that deformed palates occurred in children who never had adenoids.

In a study of 800 children who underwent adenoidectomy or tonsillectomy Whitaker (1911) found that only about 30% had had dental anomalies that called for orthodontic treatment. Whitaker has also suggested that maxillary contraction with irregular dentition and the presence of adenoids and hypertrophic tonsils are both a consequence of thyroid hormone deficiency. Besides leading to impaired calcification of the jaws, this deficiency activates the organism's defense mechanisms, including hypertrophy of lymphoid tissue. Whitaker has pointed out, moreover, that the simultaneous occurrence of mouth breathing and some form of malocclusion does not necessarily indicate a causal connection.

Nordlund (1918) investigated 61 individuals with adenoids and found that their upper jaw was characterized by a high, narrow palate. This was interpreted as a consequence of a leptoprosopic inheritance.

Nor could Wallace (1927) find sufficient evidence that the occurrence of adenoids leads to a particular type of dentition.

Brash (1929) like McKenzie, found that a small high palate occurred frequently among children who had never been troubled by adenoids.

Howard (1932) studied the status of the dentition of 159 children who were mouth breathers as a result of adenoids or enlarged tonsils. Only 13.9% belonged to Angle class II, 1 i.e. the dentition often associated with mouth breathing in the literature, while 80.4% had a normal dentition and 5.7% belonged to Angle class III.

Sillman (1942) conducted a longitudinal study on children from birth to 5 years of age and did not find that adenoids and mouth breathing constitute a primary etiological factor in malocclusions.

In a review of the literature on mouth breathing as a cause of special types of dentition, Hartsook (1946) concluded that mouth breathing is not a primary etiological factor in any type of malocclusion.

Since various types of dentition are found

Review of the literature

The various opinions encountered in the literature as to a possible relationship between adenoids on the one hand and on the other special facial expressions types of dentition and mouth breathing can be grouped as follows.

1 The combination of adenoids and mouth breathing gives rise to a special facial expression and type of dentition

2 The combination of adenoids and mouth breathing does not affect the facial expression and type of dentition.

3 Adenoids lead to mouth breathing in cases with particular facial characteristics and types of dentition

1 The combination of adenoids and mouth breathing gives rise to a special facial expression and type of dentition

The blocking of the nasopharynx by adenoids with the diminution or cessation of nasal breathing has been presented as a mechanism to explain the alteration of normal growth and development of the jaws. The assumption is that the absence of nasal breathing may indirectly affect the form of the maxillary arch through interference with the growth of the upper facial skeleton as a whole and with the floor of the nasal cavities in particular.

Once attention had been drawn by Meyer (1868) to the deleterious effect of adenoids on the hearing as well as on the general condition of a growing child, only a few years passed before Tomes (1872) reported that children who are mouth breathers on account of large adenoids usually display contracted, V-shaped dental arches. This form of jaw has been attributed to the circumstance that mouth breathers keep the lips parted and the tongue

low the theory being that imbalance between pressure from the tongue and the cheek muscles results in the alveolar process in the premolar region being pressed medially by the cheek muscles at the same time as the anterior part of the upper jaw is pressed forwards. This line of reasoning has been termed the *compression theory* (Nordlund, 1918). Many other authors, e.g. Angle (1907), Kärbitz (1910), Izard (1925), Bowen & Balyeat (1934), Nevert (1939), Cooke (1940), McCoy (1941), Hemley (1944), Massler, Poncher & Schour (1945), Subtelny (1954), Negus (1955), Duyzng (1963) and Moyers (1963) appear to be of much the same opinion when they maintain that the *direct cause of the deformation of the alveolar process in mouth breathers*, partly as a consequence of adenoids lies in the atypical movements of the tongue or other facial muscles that are usually associated with mouth breathing.

Körner (1891) and Bentzen (1903) have suggested that mouth breathing in association with adenoids, besides leading to narrow dental arches, may also give rise to compression of the upper jaw. According to this view the height of the palatal vault increases to the same extent as the nasal cavity becomes atrophied as a result of inactivity. This has been termed the *inactivity theory* (Nordlund, 1918).

Bloch (1903) and Michel (1908) believed that the high palate which develops when there is an impediment to nasal breathing, is a result of the upward direction of the air stream, which impinges on the palate in mouth breathing. This has been termed the *excavation theory* (Nordlund 1918).

Kantorowicz (1916) and Wustrow (1917) have expressed the view that the high palate

In cases with mouth breathing and nasal obstruction is due to the raised negative air pressure in the nasal cavity and the resulting increased difference between the pressure in the mouth and nasal cavity.

Joshi (1964) found in 387 children that oronasal breathers, in association with enlarged tonsils and adenoids, are far more likely to develop Angle class II. 1 than nasal breathers.

Ricketts (1968) reporting that adenoid children displayed definite characteristics in facial expression and type of dentition, termed these observations "the respiratory obstruction syndrome". Characteristic findings in these children, who are mouth breathers are considered to be protrusion of the tongue between the upper and lower incisors in swallowing, the occurrence of open bite uni- or bi-lateral crossbite and the head tilted backwards some what. Furthermore, unilateral crossbite is reported to have corrected spontaneously in three patients after adenoidectomy.

2 The combination of adenoids and mouth breathing does not affect the facial expression and type of dentition

Several authors have reported that so-called adenoid facies is not always associated with adenoids and mouth breathing, and that a particular type of dentition is not always found in mouth breathers with or without adenoids.

As early as 1888 Kingsley stated that he could not accept the view that muscular contraction of the cheeks could produce a contraction of the palate. He felt that the V-shaped palate was inherited and not acquired through mouth breathing.

In connection with extensive facial measurements, Siebenmann (1897) found that adenoids commonly occur in leptoprosopic individuals but were not therefore etiologically responsible for this form of face.

McKenzie (1909) investigated 2... children with adenoids and found that over 40% had normal palates and that deformed palates occurred in children who never had adenoids.

In a study of 800 children who underwent adenoidectomy or tonsillectomy Whitaker (1911) found that only about 30% had had dental anomalies that called for orthodontic treatment. Whitaker has also suggested that maxillary contraction with irregular dentition and the presence of adenoids and hypertrophic tonsils are both a consequence of thyroid hormone deficiency. Besides leading to impaired calcification of the jaws, this deficiency activates the organism's defense mechanisms including hypertrophy of lymphoid tissue. Whitaker has pointed out, moreover that the simultaneous occurrence of mouth breathing and some form of malocclusion does not necessarily indicate a causal connection.

Nordlund (1918) investigated 61 individuals with adenoids and found that their upper jaw was characterized by a high, narrow palate. This was interpreted as a consequence of a leptoprosopic inheritance.

Nor could Wallace (1927) find sufficient evidence that the occurrence of adenoids leads to a particular type of dentition.

Brush (1929), like McKenzie, found that a small high palate occurred frequently among children who had never been troubled by adenoids.

Howard (193...) studied the status of the dentition of 159 children who were mouth breathers as a result of adenoids or enlarged tonsils. Only 13.9% belonged to Angle class II. 1. i.e. the dentition often associated with mouth breathing in the literature, while 80.4% had a normal dentition and 5.7% belonged to Angle class III.

Sillman (1942) conducted a longitudinal study on children from birth to 5 years of age and did not find that adenoids and mouth breathing constitute a primary etiological factor in malocclusions.

In a review of the literature on mouth breathing as a cause of special types of dentition, Hartsook (1946) concluded that mouth breathing is not a primary etiological factor in any type of malocclusion.

Since various types of dentition are found

Review of the literature

The various opinions encountered in the literature as to a possible relationship between adenoids on the one hand and, on the other special facial expressions, types of dentition and mouth breathing can be grouped as follows

1 The combination of adenoids and mouth breathing gives rise to a special facial expression and type of dentition

2 The combination of adenoids and mouth breathing does not affect the facial expression and type of dentition

3 Adenoids lead to mouth breathing in cases with particular facial characteristics and types of dentition

1 The combination of adenoids and mouth breathing gives rise to a special facial expression and type of dentition

The blocking of the nasopharynx by adenoids with the diminution or cessation of nasal breathing has been presented as a mechanism to explain the alteration of normal growth and development of the jaws. The assumption is that the absence of nasal breathing may indirectly affect the form of the maxillary arch through interference with the growth of the upper facial skeleton as a whole and with the floor of the nasal cavities in particular.

Once attention had been drawn by Meyer (1868) to the deleterious effect of adenoids on the hearing as well as on the general condition of a growing child only a few years passed before Tomes (1872) reported that children who are mouth breathers on account of large adenoids usually display contracted, V-shaped dental arches. This form of jaw has been attributed to the circumstance that mouth breathers keep the lips parted and the tongue

low the theory being that imbalance between pressure from the tongue and the cheek muscles results in the alveolar process in the premolar region being pressed medially by the cheek muscles at the same time as the anterior part of the upper jaw is pressed forwards. This line of reasoning has been termed the *compression theory* (Nordlund 1918). Many other authors, e.g. Angle (1907) Kärbitz (1910) Izard (1925) Bowen & Balyeat (1934) Neivert (1939) Cooke (1940) McCoy (1941) Hemley (1944) Massler Poncher & Schour (1945) Subtelny (1954) Negus (1955) Duyzing (1963) and Moyers (1963) appear to be of much the same opinion when they maintain that the direct cause of the deformation of the alveolar process in mouth breathers, partly as a consequence of adenoids lies in the atypical movements of the tongue or other facial muscles that are usually associated with mouth breathing.

Körner (1891) and Bentzen (1903) have suggested that mouth breathing in association with adenoids besides leading to narrow dental arches, may also give rise to compression of the upper jaw. According to this view the height of the palatal vault increases to the same extent as the nasal cavity becomes atrophied as a result of inactivity. This has been termed the *inactivity theory* (Nordlund, 1918).

Bloch (1903) and Michel (1908) believed that the high palate which develops when there is an impediment to nasal breathing, is a result of the upward direction of the air stream, which impinges on the palate in mouth breathing. This has been termed the *excavation theory* (Nordlund 1918).

Kantorowicz (1916) and Wustrow (1917) have expressed the view that the high palate

nessed in relation to the size of the skeletal nasopharyngeal cavity

Subtelny (1954) strongly emphasized that not all adenoid children are mouth breathers. Mouth breathing is not considered to arise unless adenoids occupy the greater part of the nasopharyngeal airway. It is also pointed out that most children who breathe through the mouth on account of adenoids display a spontaneous return to nose breathing as the lymphoid tissue becomes atrophic and the nasopharynx grows.

It has been pointed out by Goldman & Bachman (1958) that the size of the nasopharynx varies considerably in different individuals. This variation provides an important explanation for the varying effect which large adenoids have on the passage of air.

Lubarth (1960) pointed out that children often had a small nasopharynx, so that nose breathing may be impeded by only a moderate enlargement of adenoids.

Discussion

As indicated above, the effect of adenoids on facial expression, types of dentition and mode of breathing has been investigated and discussed by a good many authors in the course of the past hundred years and diverse opinions have been expressed as to the importance of adenoids for the development of the individual's face and dentition.

A review of the literature on this subject during this period gives the impression that several theories which were constructed on a weak foundation at an early stage have since been repeated on several occasions. In most of the cases in which the opinions have been based on investigations, the presentation of the material and methods leaves a good deal to be desired. In the majority of cases the investigations have simply taken the form of frequency studies.

Only a few reports indicate how the adenoids have been assessed. The possibilities of radiographic diagnosis were recognized at an early stage, however and were described by Mignon (1898) soon after the clinical value of x-rays became apparent.

Moreover there are few articles which indicate whether the various investigations were conducted in collaboration with an otologist.

Only some authors describe how they registered mouth breathing. In these cases this was done with the help of a cold mirror, tissue paper or a metal spatula held alternately in front of the nose and mouth.

Judging from the available literature, therefore, the relationship between adenoids on the one hand and adenoid facies, special types of dentition and mouth breathing on the other has so far been studied objectively to only a limited extent. In those cases in which measurements have been made, the analysis has been confined to simple methods for calculating means and percentages.

among mouth breathers, it cannot be said that there is one particular or classic type of malocclusion.

Similar opinions were expressed by Huber & Reynolds (1946) after a study on 27 mouth-breathing students, of whom one had an anatomically correct dentition, 15 Angle class I 8 Angle class II and 2 Angle class III.

In studies covering more than 15 years, Ballard & Gwynne Evans (1958) investigated the relationship between jaw form, soft tissue morphology and mode of breathing. Their results suggest that oral and facial morphology remains strikingly constant during growth. Consequently they consider that mouth breathing does not cause jaw deformities and malocclusions and nor does it therefore lead to so-called adenoid facies. They believe that individuals displaying the syndrome of adenoid facies, contracted maxilla, narrow nasal airways and malocclusions belong to a particular morphological type. They usually have a long face, high gonion angle, a narrow U- or V shaped upper dental arch and a high palate. The narrow upper jaw results in narrow nasal passages and consequently nasal breathing is more likely to be impeded in infections involving swollen nasal mucosa.

In an investigation on 500 patients at an ear nose and throat department, Lecch (1958) reported that a postnormal occlusion was somewhat more common than other types of dentition among the patients with adenoids. A particularly interesting finding was that Angle class II 2 occurred more frequently than Angle class II 1 although the difference was not statistically significant. The study also showed that only 10% of the adenoid individuals had a narrow upper jaw. Mouth breathing was found in only 19% of these children.

In a study of 297 patients Linder Aronson & Bäckström (1960) found that adenoids occurred in connection with high as well as low index values for the relationship between face breadth and height as well as between palatal breadth and height.

Tulley (1966) reported that the work of the

Upper Respiratory Research Unit at Guy's Hospital, London, has shown that clinical types, who may or may not have any upper respiratory defects, e.g. obstructive pad of adenoids, can be recognized from the so-called adenoid facies. This is an inherited facies.

3 Adenoids lead to mouth breathing in cases with particular facial characteristics and types of dentition

The effect of adenoids on the mode of breathing is considered by several authors to vary according to the type of face and dentition. The nasopharyngeal volume has been considered particularly important in this context.

After extensive facial and palatal measurements, Siebmann (1897) maintained that a high palate is commonly found in individuals with a narrow face and constricted nasal cavities. In individuals with a narrow nose and small nasopharyngeal volume, adenoids often cause mouth breathing.

Nordlund (1918) studied 61 patients and found that discomfort from adenoids, e.g. in the form of mouth breathing, is more pronounced among individuals with a high narrow palate and narrow nose than among those with a broad palate and nasal structure.

The importance of the nasopharyngeal volume has been emphasized by Bernfeld (1927) in cases of adenoids with nasal obstruction.

Brash (1929) suggested that discomfort from adenoids may be a simple indication of insufficient space in the nasopharyngeal region.

Schüller (1929) simply stated that epipharyngeal tumours, among which he included adenoids, cause a greater obstruction if the epipharyngeal cavity is small and narrow.

Emalie Massler & Zwemer (1952) noted that in children with a narrow nasopharyngeal passage, even physiological enlargement of lymphoid tissue in the nasopharyngeal region may act as an obstruction and lead to mouth breathing.

Ricketts (1954) suggested that adenoids are important for respiration only if they are as-

ceased in relation to the size of the skeletal nasopharyngeal cavity

Subtelny (1954) strongly emphasized that not all adenoid children are mouth breathers. Mouth breathing is not considered to arise unless adenoids occupy the greater part of the nasopharyngeal airway. It is also pointed out that most children who breathe through the mouth on account of adenoids display a spontaneous return to nose breathing as the lymphoid tissue becomes atrophic and the nasopharynx grows.

It has been pointed out by Goldman & Bachman (1958) that the size of the nasopharynx varies considerably in different individuals. This variation provides an important explanation for the varying effect which large adenoids have on the passage of air.

Lubart (1960) pointed out that children often had a small nasopharynx, so that nose breathing may be impeded by only a moderate enlargement of adenoids.

Discussion

As indicated above, the effect of adenoids on facial expression, types of dentition and mode of breathing has been investigated and discussed by a good many authors in the course of the past hundred years and diverse opinions have been expressed as to the importance of adenoids for the development of the individual's face and dentition.

A review of the literature on this subject during this period gives the impression that several theories which were constructed on a weak foundation at an early stage have since been repeated on several occasions. In most of the cases in which the opinions have been based on investigations, the presentation of the material and methods leaves a good deal to be desired. In the majority of cases the investigations have simply taken the form of frequency studies.

Only a few reports indicate how the adenoids have been assessed. The possibilities of radiographic diagnosis were recognized at an early stage, however and were described by Mignon (1898) soon after the clinical value of x-rays became apparent.

Moreover there are few articles which indicate whether the various investigations were conducted in collaboration with an otologist.

Only some authors describe how they registered mouth breathing. In these cases this was done with the help of a cold mirror, tissue paper or a metal spatula held alternately in front of the nose and mouth.

Judging from the available literature, therefore, the relationship between adenoids on the one hand and adenoid faces, special types of dentition and mouth breathing on the other has so far been studied objectively to only a limited extent. In those cases in which measurements have been made, the analysis has been confined to simple methods for calculating means and percentages.

Material and methods

MATERIAL

The present investigation was conducted on 162 children from the county of Örebro in Central Sweden. Of these children, 81 were patients and 81 served as controls.

The patients were all children born in the years 1955-61 who attended the Otorhinolaryngologic Department of Örebro Regional Hospital in the period 1 October 1966-30 September 1967 and were judged to present indications for adenoidectomy. This assessment was made by one of the six otologists at the Department. The distribution by year of birth and sex for all adenoidectomy cases during this period is shown in Fig. 1. The majority of the children presenting indications for adenoidectomy were about 8 years old. The sex ratio is 60% boys and 40% girls. This ratio has been compared with the sex distribution for the children who underwent adenoidectomy during 1967 at the Regional and University Hospital in Linköping (56% boys and 44% girls). The sex difference is not significant.

During the period in question, a total of 166 patients born in the years 1954-61 underwent adenoidectomy at Örebro Regional Hospital, representing 0.9% of the population. The 81 patients who form the subjects of the present investigation constitute 0.4% of the population. The difference between the total number of adenoidectomy patients and the present group of subjects amounts to 85 patients. This drop-out is explained as follows:

(a) The 35 patients belonging to the Lindenberg district were not included for practical reasons.

(b) The 13 patients who underwent adenoidectomy at the regional hospital but whose

treatment was otherwise in the hands of private specialists were not included either.

(c) Adenoidectomy was performed on 30 patients at the regional hospital without the Orthodontic Department at Örebro being informed.

(d) Adenoidectomy was performed on 7 patients at the regional hospital at times when data could not be registered at the Orthodontic Department before the operation.

The control group was made up to conform in the age, sex and number of the adenoidectomy children. Thus the controls were selected by taking the child resident in Örebro whose national registration number came closest after that of one of the adenoidectomy children of the same sex. This means that the controls were of practically the same age as the patients. The controls were confined to residents of Örebro in order to make it easier for these children to participate in the investigation.

Further selection criteria for the controls were that they had no history of obstructed nose breathing, allergy or recurrent otitis media and infections that they had never undergone adenoidectomy or received orthodontic treat-

Fig. 1 Distribution of the total material by sex and year of birth. The investigation was made in the period 1 October 1966-30 September 1967.

Aim of the present investigation

In view of the divergency of opinions concerning the relationship of adenoids to mode of breathing and special types of facial expression and dentition—and consequently also the uncertainty as to whether adenoidectomy can be expected to influence the status of the dentition—the present investigation was conducted with the primary aim of using objective methods of registration together with correlation analysis and multiple regression analysis to study what effect the presence of adenoids has on variables that represent airflow mode of breathing and type of dentition.

At the same time an attempt is made to study the relationship between these variables and certain variables for the facial skeleton.

The investigation also includes an analysis of the possibility of a connection between adenoids and so-called adenoid facies.

The question of whether changes in tongue position are of etiological importance for malocclusions in the presence of adenoids is approached by studying the correlations between variables for tongue position and variables for size of adenoids and dentition. In this context particular attention is paid to the variables for arch width, arch length, height of palatal vault, and inclination of upper and lower incisors.

The relationship between size of adenoids and the values for the dentition variables was studied on the basis of the following working hypothesis.

Enlarged adenoids gives rise to mouth breathing, which leads in turn to a change in tongue position and this is then followed by changes that are reflected in the dentition variables.

Material and methods

MATERIAL

The present investigation was conducted on 162 children from the county of Örebro in Central Sweden. Of these children, 81 were patients and 81 served as controls.

The patients were all children born in the years 1955–61 who attended the Otorhinolaryngologic Department of Örebro Regional Hospital in the period 1 October 1966–30 September 1967 and were judged to present indications for adenoidectomy. This assessment was made by one of the six otologists at the Department. The distribution by year of birth and sex for all adenoidectomy cases during this period is shown in Fig. 1. The majority of the children presenting indications for adenoidectomy were about 8 years old. The sex ratio is 60% boys and 40% girls. This ratio has been compared with the sex distribution for the children who underwent adenoidectomy during 1967 at the Regional and University Hospital in Linköping (56% boys and 44% girls). The sex difference is not significant.

During the period in question, a total of 166 patients born in the years 1955–61 underwent adenoidectomy at Örebro Regional Hospital, representing 0.9% of the population. The 81 patients who form the subjects of the present investigation constitute 0.4% of the population. The difference between the total number of adenoidectomy patients and the present group of subjects amounts to 85 patients. This drop-out is explained as follows.

(a) The 35 patients belonging to the Lindesberg district were not included for practical reasons.

(b) The 13 patients who underwent adenoidectomy at the regional hospital but whose

treatment was otherwise in the hands of private specialists were not included either.

(c) Adenoidectomy was performed on 30 patients at the regional hospital without the Orthodontic Department at Örebro being informed.

(d) Adenoidectomy was performed on 7 patients at the regional hospital at times when data could not be registered at the Orthodontic Department before the operation.

The control group was made up to conform to the age, sex and number of the adenoidectomy children. Thus the controls were selected by taking the child resident in Örebro whose national registration number came closest after that of one of the adenoidectomy children of the same sex. This means that the controls were of practically the same age as the patients. The controls were confined to residents of Örebro in order to make it easier for these children to participate in the investigation.

Further selection criteria for the controls were that they had no history of obstructed nose breathing, allergy or recurrent otitis media and infections, that they had never undergone adenoidectomy or received orthodontic treat-

Fig. 1 Distribution of the total material by sex and year of birth. The investigation was made in the period 1 October 1966–30 September 1967.

Fig. 2 Grouping by size of adenoids as studied on lateral cephalometric radiographs. 1 = no adenoids, 2 = small or moderate adenoids, 3 = large adenoids.

ment and were willing to take part in the study. If these criteria were not fulfilled by the child whose registration number came closest after an adenoidectomy child—as happened in five cases—then the child of the same sex with the next nearest number who met the criteria was selected instead. Of the five children who did not meet the criteria, one had previously received orthodontic treatment, two had previously undergone adenoidectomy and two had had such discomfort from nose breathing that an otologist had considered that adenoidectomy was indicated (these two were later included among the adenoidectomy patients).

The control group, which comprises children from the city of Örebro, represents about 1% of the population of Örebro city born in the years 1955–61.

The controls were examined at the Otorhinolaryngologic Department either by the Head or the Deputy Head Otologist.

Grouping

The controls were grouped according to the size of the adenoids as assessed on lateral radiographs (cf. Fig. 2).

Group 1 No adenoids 37 children.

Group 2. Small or moderate adenoids. 33 children.

Group 3 Large adenoids. 11 children.

The adenoidectomy patients were grouped according to the indication for the operation.

Group 4 Adenoidectomy as a result of recurrent otitis media. 21 children.

Group 5 Adenoidectomy as a result of obstructed nose breathing. 60 children.

Patients with both these indications were referred to group 5.

The selection of patients for groups 4 and 5 was undertaken by the otologists and is thus based upon clinical observations as to the presence of adenoids as well as the presence of ear, nose and throat complaints in the form of recurrent otitis media and obstructed nose breathing. The controls, on the other hand, were grouped solely according to the size of the adenoids as assessed by the author from lateral radiographs.

Variables

In order to make the investigation as comprehensive as possible 173 variables were chosen preliminarily as being possibly relevant and were studied in all the patients in the material. Statistical processing of the results showed however that the number of variables could be reduced to 131. The variables excluded are those which correlation analysis proved to be irrelevant in the present context, particularly in relation to the airflow mode of breathing and dentition variables. The majority of those excluded were index variables.

The final list of 131 variables, which is presented and defined in Table 1 and on pages 13–15, can be divided into the following groups.

Group An 19 variables concerning the anamnesis and clinical status. This group comprises all the anamnestic and status data noted by the otologists and/or the author at the first examination.

Group Ad. 22 adenoid variables. This group covers the various indications for adenoidectomy.

Table 1 *The variables and their definitions*

The variables are arranged in seven groups. *An*, anamnesis and clinical variables; *Ad*, adenoid variables; *D*, dentition variables; *F*, airflow variables; *G*, variable for grouping the children; *S*, skeleton and lip variables; *T*, variables for tongue position

Fig 4 Cephalostat according to Thörne modified for exact measurement of the angle between the Frankfort plane and the horizontal plane on postero-anterior cephalometric radiographs.

called adenoid facies (cf. Fig. 3 for a description see p. 5) varied between the patient and control groups. The occurrence of adenoid facies was assessed independently by an otologist and an orthodontist.

Measurements on the radiographs

The following radiographs were taken in each child: two lateral cephalometric radiographs with the teeth occluded, two with the lower jaw in the rest position and two postero-anterior radiographs with the teeth occluded. For the lateral radiographs the exposure times were 0.4 or 0.5 sec, while for the postero-anterior radiographs they were 1.0 or 1.2 sec, the exposure being adapted to the age of the individual.

The radiographs were taken with a Philips Rotapraetix apparatus with a film-focus distance of 165 cm and a rotating anode tube with a focus of 1.2 mm. The exposures were made with 100 kV and 50 mA.

The radiographs were taken with the subject's head immobilized in a cephalostat ad modum Thörne (1951).

For the profile films the subject was seated

with the left side facing the film. The head was fixed in the cephalostat with the median plane parallel to the film and 10 cm from it, and an aluminum filter wedge shaped in cross-section, was placed between the facial profile and the film to reduce the dosage in this area. The central ray passes through two rods inserted in the external ear channel. The enlargement of the median plane with this arrangement is 6.5%.

For the postero-anterior films the subject was seated with the face turned to the film. The head was fixed in the cephalostat in two different positions: (1) The head was oriented with the Frankfort plane horizontal (2) the head had been rotated in a forward direction $\approx 26^\circ$ between the Frankfort plane and the horizontal plane (see Fig. 4). The ear rods were placed 12 cm from the film. The enlargement of a plane through the ear rods is then 7.8%.

Definitions of the measurements on the radiographs

The measurements on the radiographs were made on Unitek tracing film no 701-204 on which the reference points were marked. All

tomy as well as measurements of the size of the adenoids

Group D: 25 dentition variables, i.e. all the variables that describe the individual's dentition

Group F: 12 airflow variables, i.e. the variables that express the nasal airflow at differential pressures of 10, 15 and 20 mm H₂O

Group G: 1 variable for grouping the subjects under five headings: 1-3 for the controls and 4-5 for the subjects of the investigation

Group S: 47 skeletal and 2 lip variables

Group T: 3 tongue variables. These variables indicate the position of the tongue in relation to the hard and soft palate

All these variables were studied in the patients as well as the controls in the following ways

1. Direct measurements on the child.
2. Lateral and frontal photographs of the face
3. Lateral and postero-anterior radiographs.
4. Casts of the upper and lower jaws
5. Recordings of nasal airflow before and 15 min after the administration of nose drops.

All the children were first examined on two occasions one month apart. In the case of the patients, the lateral radiography and airflow measurements were repeated at the second examination, which took place one month after adenoidectomy. In the controls, however, only the airflow measurements were repeated.

In addition, all the children have been followed up one year after the second examination. In order to keep the present report within reasonable limits, however, this part of the investigation will be presented separately.

MEASUREMENTS

Direct measurements

Five direct measurements were made on each child represented by the following variables.

A80 Width of face between two points 15 mm lateral of the lateral angle of either eye

Fig. 3 So-called adenoid facies.

A81 Height of face between the midpoint of the line joining the medial angles of either eye and the lower edge of the lower jaw

A82 Width of nose over alae nasi

A83 Width of nose above alae nasi

A84 Height of upper lip between the columella nasi and the lower edge of the upper lip in the median plane.

Variables A80-83 were measured with a modified calliper rule to an accuracy of ± 0.1 mm. Variable A84 was measured with a conventional caliper rule with the same accuracy.

Photographs of the face

Frontal and profile photographs were taken of the face in every case from a distance of 1 m. These photographs were used to investigate whether the frequency of individuals with so-

Fig. 7 Reference points and linear measurements on postero-anterior cephalometric radiographs with the Frankfort plane horizontal.

- lml Left zygomaticofrontal suture—the most lateral point in the zygomaticofrontal suture (Marble 1922).
fml-fmr Distances between first molars on either side (A98).
lo Lateral-orbitale—intersection of the oblique line and the orbital margin (Sassouni 1960).
l-l Distances between l on either side (A99).

Fig. 8 Reference points and linear measurements on postero-anterior cephalometric radiographs with the head rotated 26° forward direction so that the Frankfort plane is at 26° to the horizontal plane.

- lml The most lateral point on the lateral wall of the nasal cavity.
lml-lml Distances between lml on either side—width of posterior choanal aperture—(A100).

Fig. 9 Reference lines on lateral cephalometric radiographs.

- ILI Lower incisor line—the axis of the lower central incisor.
ILS Upper incisor line—the axis of the upper central incisor.
ML Mandibular line—the tangent to the lower border of the mandible through gonion. (If the lower border of the mandible presented a double contour the mandibular line was taken to be line midway between the tangents to the two contours.)
NL Nasal line—the line through tip and post-nasion.
NSL Nasion-sella line—the line through nasion and sella.
OLI Occlusal line—the line through the midpoint of the distance between the incisal edges of the upper and lower central incisors and the distobuccal cusp of the first upper molar. (If the first upper molar presented double contour point was chosen midway between the double contours of the apices of the distobuccal cusps.)

Indexes for skeletal variables measured on cephalometric radiographs

In addition to the measurement of lines and angles, indexes were calculated for relationships between variables for widths, heights and lengths in the face and nasopharynx. The measurements were made on cephalometric radiographs and the indexes are expressed as percentages.

Fig 5 The Ingut 9544-11 planimeter type OTT for measuring the area of adenoids and the bony nasopharynx.

linear measurements were read to the nearest tenth of a millimetre

The angles were measured between lines defined by reference points. All the readings were made to the nearest half degree

Free way space (A43) is the difference between the distance n - gn at rest and in occlusion

Area measurements of the size of adenoids and the size of the bony nasopharyngeal cavity (see p 21) were made with an Ingut 9544-11 planimeter type OTT to within ± 2 sq mm (see Fig 5)

The various reference points and lines as well as the linear and angular measurements on the cephalometric radiographs are indicated in Figs 6-11 and defined in the text to these figures

Fig 6 Reference points on lateral cephalometric radiographs.

- ad Intersection of the line pm - ba and the posterior nasopharyngeal wall.
- ad Intersection of the line pm - ho and the posterior nasopharyngeal wall.
- ad₂ Intersection of the line ba - ho and the posterior nasopharyngeal wall.
- ba Basion—the most postero-inferior point on the clivus of os occipitale.

- gn Gnathion—the point on the inferior limit of the symphysis furthest from nasion.
- ho Hornion—the vomer's most dorsal contact point on the body of the sphenoid bone in the midsagittal plane, between the slope of the vomer (Martin, 1928).
- ho The point corresponding to the point ho on the opposite side of the line pm - ba .
- n Nasion—the most anterior point of the frontonasal suture.
- pm pterygomaxillare—the intersection between the nasal floor and the posterior contour of the maxilla.
- a Sella—the centre of the sella turcica. the upper limit of the sella turcica is defined as the line joining the tuberculum and dorsum sellae.
- a The projection of a on the line pm - ba .
- sm Supramentale—the most posterior point on the anterior contour of the lower alveolar arch (the head being oriented with the Frankfort plane parallel to the horizontal plane).
- sp Spinal point—the apex of the anterior nasal spine.
- sp Intersection of the nasal line sp - pm and the line nasion-gnathion.
- ss Subspinale—the most posterior point on the anterior contour of the upper alveolar arch (the head being oriented with the Frankfort plane parallel to the horizontal plane).
- ss The projection of ss on the nasal line.
- t Intersection of a line perpendicular to the nasion-sella line through pterygomaxillare and the contour of the tongue.
- t Intersection of the contour of the tongue and a line through basion perpendicular to the sella basion line.
- t₂ Intersection of the contour of the tongue and a line through the midpoint of and perpendicular to the line pm - v .
- v The most postero-inferior point of the soft palate (tip of the uvula).

Fig 11 Angular measurements on lateral cephalometric radiographs.

- s-a-s Sella-nasion-subnasale—angle between apical base of maxilla and the line nasion-sella (A102).
- s-o-sm Sella-nasion-supramentale—angle between apical base of mandible and the line nasion-sella (A103).
- ss-o-sm Subnasale-nasion-supramentale—postero-anterior angle between the lines from nasion to the apical base points on the upper and lower jaws (A105).
- ML/NL Mandibular line/Nasion-sella line—relative dimension between anterior and posterior face height (A106).
- NL/NL Mandibular line/Nasal line—relative dimension between anterior and posterior lower face height (A107).
- NL/NL Nasal line/Nasion-sella line—relative dimension between anterior and posterior upper face height (A108).

decal to the line pm-v through the midpoint of this line (A131).

Height of upper lip—the shortest distance from the contour of the upper lip to the nasal line (A96).

Height of lower lip—the shortest distance from the contour of the lower lip to the mandibular line (A97).

Relationship between length of basis maxillae and face height.

$$\frac{sa-pm (A91)}{n-gn (A88)} \times 100 \quad (115)$$

Relationship between upper and total face height.

$$\frac{n-sp (A89)}{n-gn (A88)} \times 100 \quad (A116)$$

Relationship between basis maxillae and upper face height.

Fig. 13 Three-dimensional calipers designed by Korkhaus (and modified by Lundström) for measuring the length of the dental arch and the height of the palatal vault.

was measured in the same way as in the upper jaw

A 2. The length of the dental arch as measured (to within ± 0.1 mm) with the three-dimensional calipers (compass) designed by Korkhaus and modified by Lundström (see Fig. 13). The measurements were made in accordance with Lundström (1948).

A 3. The space-difference of the dental arch. The difference between the circumference of the dental arch from second molar to second molar and the sum of the mesiodistal diameter of first molar, premolars, canines and incisors. The mesiodistal tooth diameter and the space of the dental arch were measured in accordance with Lundström (1948) (see Fig. 14).

Fig. 14 Measuring the space in the dental arch. After Lundström.

B 1. The height of the palatal vault, i.e. to its highest point, was measured at right angles to the plane of occlusion, in the line joining the measuring points on the first molars. The three-dimensional compass was used for this measurement as well, placed in the same way as in measurement of the length of the dental arch (see Fig. 15). The measurements were made in accordance with Lundström (1948), with an accuracy of ± 0.1 mm.

C 1. The overjet was measured, with an accuracy of ± 0.1 mm, at the central incisors, using the sliding calipers. The overjet was taken as the mean of the distance from the midpoint of the edge of the left upper central incisor to the labial surface of the left lower central incisor and of the corresponding distance between the right upper central incisor

and right lower central incisor. The relevant distance was measured parallel to the plane of occlusion, at right angles to the dental arch (see Fig. 16).

C 2. The overbite was also measured at the central incisors. It is given as the mean of the distance from the edge of the left lower central incisor to the point on its labial surface on which the sliding calipers impinged in measurement of the overjet, and of the corresponding distance on the right lower central incisor. A horizontal groove was drawn through this point (see Fig. 16). Using the sliding calipers, the distance was measured with an accuracy of ± 0.1 mm. A frontally open bite is denoted by a negative value, and the reverse by a positive value.

C 3. The molar occlusion was taken as the

Fig. 12 Measuring points for width and length of dental arches. After Lundström.

Measurements on the casts

Impressions of the upper and lower dental arches were taken in *Tissuotex* alginate material and plaster models made. A wax record in maximum intercuspitation was also taken.

The following 14 measurements were made on the models

A. In the upper and lower jaws

- 1 Width of dental arch between first molars (A49 50) first deciduous molars (A51 52)
- 2 Length of dental arch (A53 54)
- 3 The space difference of the dental arch (A61 62)

B. In the upper jaw only

- 1 Height of palatal vault (A60)

C. Upper and lower dental arches in occlusion.

- 1 Overjet (A55)
- 2 Overbite (A56)
- 3 Molar occlusion (A57 58)

The transverse relation (A59) between the jaws was evaluated on the models without measurements

A 1 The width of the dental arch in the upper jaw was measured (with an accuracy of ± 0.1 mm) with sliding calipers at the first molars, and the first deciduous molars in accordance with Lundström (1948) (see Fig. 12). The width of the dental arch in the lower jaw

Fig. 13 Three-dimensional calipers designed by Korkhaus (and modified by Lundström) for measuring the length of the dental arch and the height of the palatal vault.

was measured in the same way as in the upper jaw

A 2. The length of the dental arch as measured (to within ± 0.1 mm) with the three-dimensional calipers (compass) designed by Korkhaus and modified by Lundström (see Fig. 13). The measurements were made in accordance with Lundström (1948)

A 3. The space-difference of the dental arch. The difference between the circumference of the dental arch from second molar to second molar and the sum of the mesiodistal diameter of first molar premolars, canines and incisors. The mesiodistal tooth diameter and the space of the dental arch were measured in accordance with Lundström (1948) (see Fig. 14)

Fig. 14 Measuring the space in the dental arch. After Lundström.

B 1. The height of the palatal vault, i.e. to its highest point, was measured at right angles to the plane of occlusion, in the line joining the measuring points on the first molars. The three-dimensional compass was used for this measurement as well, placed in the same way as in measurement of the length of the dental arch (see Fig. 15). The measurements were made in accordance with Lundström (1948) with an accuracy of ± 0.1 mm.

C 1. The overjet was measured, with an accuracy of ± 0.1 mm, at the central incisors, using the sliding calipers. The overjet was taken as the mean of the distance from the midpoint of the edge of the left upper central incisor to the labial surface of the left lower central incisor and of the corresponding distance between the right upper central incisor

and right lower central incisor. The relevant distance was measured parallel to the plane of occlusion, at right angles to the dental arch (see Fig. 16)

C 2. The overbite was also measured at the central incisors. It is given as the mean of the distance from the edge of the left lower central incisor to the point on its labial surface on which the sliding calipers impinged in measurement of the overjet, and of the corresponding distance on the right lower central incisor. A horizontal groove was drawn through this point (see Fig. 16). Using the sliding calipers, the distance was measured with an accuracy of ± 0.1 mm. A frontally open bite is denoted by a negative value, and the reverse by a positive value

C 3. The molar occlusion was taken as the

$$\frac{ss-pm (A91)}{n-sp (A89)} \times 100 \quad (A117)$$

Fig. 12 Measuring points for width and length of dental arches. After Lundström.

Measurements on the casts

Impressions of the upper and lower dental arches were taken in "Tissuetex" alginate material and plaster models made. A wax record in maximum intercuspitation was also taken.

The following 14 measurements were made on the models.

A. In the upper and lower jaws

- 1 Width of dental arch between first molars (A49 50) first deciduous molars (A51 52)
- 2 Length of dental arch (A53 54)
- 3 The space difference of the dental arch (A61 62)

B. In the upper jaw only

- 1 Height of palatal vault (A60)

C. Upper and lower dental arches in occlusion

- 1 Overjet (A55)
- 2 Overbite (A56)
- 3 Molar occlusion (A57 58)

The transverse relation (A59) between the jaws was evaluated on the models without measurements.

A 1 The width of the dental arch in the upper jaw was measured (with an accuracy of ± 0.1 mm) with sliding calipers at the first molars, and the first deciduous molars in accordance with Lundström (1948) (see Fig. 12). The width of the dental arch in the lower jaw

Fig. 13 Three-dimensional calipers designed by Korkhaus (and modified by Lundström) for measuring the length of the dental arch and the height of the palatal vault.

was measured in the same way as in the upper jaw

A 2. The length of the dental arch as measured (to within ± 0.1 mm) with the three dimensional calipers (compass) designed by Korkhaus and modified by Lundström (see Fig. 13). The measurements were made in accordance with Lundström (1948).

A 3. The space-difference of the dental arch. The difference between the circumference of the dental arch from second molar to second molar and the sum of the mesiodistal diameter of first molar premolars, canines and incisors. The mesiodistal tooth diameter and the space of the dental arch were measured in accordance with Lundström (1948) (see Fig. 14).

Fig. 14 Measuring the space in the dental arch. After Lundström.

B 1. The height of the palatal vault, i.e. to its highest point, was measured at right angles to the plane of occlusion, in the line joining the measuring points on the first molars. The three-dimensional compass was used for this measurement as well, placed in the same way as in measurement of the length of the dental arch (see Fig. 15). The measurements were made in accordance with Lundström (1948), with an accuracy of ± 0.1 mm.

C 1. The overjet was measured, with an accuracy of ± 0.1 mm, at the central incisors, using the sliding calipers. The overjet was taken as the mean of the distance from the midpoint of the edge of the left upper central incisor to the labial surface of the left lower central incisor and of the corresponding distance between the right upper central incisor

and right lower central incisor. The relevant distance was measured parallel to the plane of occlusion, at right angles to the dental arch (see Fig. 16).

C 2. The overbite was also measured at the central incisors. It is given as the mean of the distance from the edge of the left lower central incisor to the point on its labial surface on which the sliding calipers impinged in measurement of the overjet, and of the corresponding distance on the right lower central incisor. A horizontal groove was drawn through this point (see Fig. 16). Using the sliding calipers, the distance was measured with an accuracy of ± 0.1 mm. A frontally open bite is denoted by a negative value and the reverse by a positive value.

C 3. The molar occlusion was taken as the

Fig 15 Measuring the height of the palatal vault. After Lundström.

distance between the mesial surfaces of the upper and lower first molars measured in the upper occlusal plane (see Fig. 17) The measurement was performed with the end of the sliding calipers. The distance was denoted as positive when the mesial surface of the upper first molar occluded distally to the mesial surface of the lower first molar.

The transverse relation between the jaws was studied only concerning the occurrence of lateral crossbite.

Indexes for dentition variables measured on casts

In addition to linear measurements on the models, indexes were calculated as percentage values for the relationship between dentition variables for breadth, height and length.

The relationship between the width of the lower and upper arches is expressed by variables A63–64. Index values close to 100 denote cusp-to-cusp dentition and higher values cross bite.

Fig 16 Measuring overjet and overbite

$$\frac{\text{Arch width } M_1-M_1 \text{ lower (A50)}}{\text{Arch width } M_1-M_1 \text{ upper (A49)}} \times 100 \quad (\text{A63})$$

$$\frac{\text{Arch width } O4-O4 \text{ lower (A52)}}{\text{Arch width } O4-O4 \text{ upper (A51)}} \times 100 \quad (\text{A64})$$

The relationship between the length and width of the upper arch is expressed by variable A65.

$$\frac{\text{Arch length upper (A53)}}{\text{Arch width } M_1-M_1 \text{ upper (A49)}} \times 100 \quad (\text{A65})$$

The relationship between height of palatal vault and width of upper arch is expressed by variable A66.

$$\frac{\text{Height of palatal vault (A60)}}{\text{Arch width } M_1-M_1 \text{ upper (A49)}} \times 100 \quad (\text{A66})$$

Recordings of nasal airflow

The nasal airflow was measured in this investigation according to the method described by Aschan et al (1958) and subsequently modified in minor respects. The recordings were made in Örebro using the original apparatus in close collaboration with these authors' technicians, who are well acquainted with the method. Together with Bäckström I have previously employed this method for measuring the nasal airflow in mouth breathing 9-year olds (Linder Aronson & Bäckström 1960). The satisfactory results on that occasion justified the use of the method in younger patients as well in order to obtain objective values for the nasal function.

The method involves the simultaneous re-

Fig 17 Measuring molar occlusion. According to Seipel.

Fig 18 Rhinometry The flow of the expiratory air is measured in plate orifice attached to the nasal mask. The pressure difference between the oral cavity and nasal openings is measured by means of polyethylene tubes in the mouth and mask.

cording of the rate of airflow and of the pressure gradient between the nasopharynx and the nostrils. A mask with insignificant dead space is held over the nose (cf Fig. 18). The pressure gradient is measured between the inside of the mask and a plastic tube introduced into the oral cavity. The subject keeps his mouth closed during the recording. Measurements on a subject free from pharyngeal reflexes have shown that the pressure in the oral cavity is practically identical with that in the nasopharynx (Aschan et al., 1958). The rate of flow is obtained by allowing the air to flow into the nose through a venturimeter (gas flow meter) connected to the mask.

The venturimeter consists of a plexiglass tube 10.8 cm long and with an inner diameter of 17.5 mm. A plate orifice 10.0 mm in diameter is fixed in the middle of the tube. Openings on each side of the plate orifice are connected by means of polyethylene tubes to both sides of a manometer. The pressure difference between the two openings provides a measure of the airflow along the tube.

The pressure difference between the mouth and the mask was measured by means of polyethylene tubes connected to another manometer. The measuring apparatus has been described by Dretzner (1961) as follows:

"The two manometers for the estimation of

flow and pressure were of the same construction but of different sensitivity. Each manometer consisted essentially of a brass membrane, which acted as a mobile plate of a double capacitor. Parallel with each of the capacitors were coils connected to resonance circuits which were supplied from an oscillator with a frequency of 425 Kc/sec. With displacements of the brass membrane, the tuning in the two resonance circuits was changed in the opposite direction. Signals from the resonance circuits were led into a differential amplifier with a symmetric input. After amplification and demodulation, the signal was passed into the DC-input of a double channel Elema mingograph model 24. The flow variations were recorded on the upper channel, and the differential pressure variations on the lower. The response time for full deflection was the same for flow and differential pressure amounting to about 0.1 sec as measured with a rapidly appearing high flow of pressure. The paper speed of the mingograph during recordings was 5 cm/sec.

The mingograph records (Fig. 19) contained the continuous recordings of the airflow through the nose (lit/min) and the differential pressure between the nasopharynx and the nostrils (mm H₂O). The recordings above the base line represent expiration, and those below the base line

Fig 15 Measuring the height of the palatal vault. After Lundström.

distance between the mesial surfaces of the upper and lower first molars measured in the upper occlusal plane (see Fig. 17) The measurement was performed with the end of the sliding calipers. The distance was denoted as positive when the mesial surface of the upper first molar occluded distally to the mesial surface of the lower first molar.

The transverse relation between the jaws was studied only concerning the occurrence of lateral crossbite.

Indexes for dentition variables measured on casts

In addition to linear measurements on the models indexes were calculated as percentage values for the relationship between dentition variables for breadth, height and length.

The relationship between the width of the lower and upper arches is expressed by variables A63–64. Index values close to 100 denote cusp-to-cusp dentition and higher values crossbite.

The method involves the simultaneous re-

Fig 17 Measuring molar occlusion. According to Serpel.

Error of methods

When assessing the error of the method, consideration must be paid to regular as well as irregular errors. Errors of method are presented below for

- 1 Anamnestic variables
- 2 Adenoid, dentition, skeleton and lip variables
- 3 Airflow variables
- 4 Variables for tongue position

1 ANAMNESIS VARIABLES

An otologist and the author made double determinations in every child of the anamnestic data A04 (Mode of breathing), A05 (Mouth open or closed in sleep), A06 (Recurrent infections in ear nose and throat), A07 (Allergy), A08 (Previous adenoidectomy), A09 (Siblings with ear nose and throat diseases)

In the case of the adenoidectomy children, the author had access to the otologist's report. The assessment of the controls, however was undertaken entirely independently by the otologist and the author. The results are presented in Tables 2 and 3

As indicated by the tables, the results of the double determinations were much the same for the operated children and the controls. It therefore seems that the author's assessments were not substantially affected by having access to the otologist's records for the adenoidectomy children.

The greatest discrepancy (10-11%) between the two assessments occurs in both groups for variable A06, Recurrent infections in the ear nose and throat. In both groups the deviation is of a regular nature in that the otologist noted recurrent infections in twice as many cases as the author.

The assessments of other anamnestic data display good agreement between the otologist and the author.

2. ADENOID DENTITION, SKELETON AND LIP VARIABLES

Double determinations in the same child have been compared in the case of measurements on pairs of radiographs taken on the same occasion, double measurements on casts and

Fig 19 Recording of the airflow through the nose (l/min) and the pressure difference between the oral cavity and the nasal openings (mm H₂O) during nasal respiration. The base line represents the zero value and the section above the base line represents expiration. Flow was measured at pressure differences of 10 15 and 20 mm H₂O before and after nose drops.

inspiration. As the response time was the same for airflow and pressure recordings, corresponding points on the same respiration section could be used to measure flow and pressure difference at a certain moment of the respiration. The airflows have been measured on the expiration section of the curve at pressure differences of 10 15 and 20 mm H₂O.

Two recordings were made, one after the

child had adapted to the climate in the examination room for about 45 minutes and the other about 15 min after inducing decongestion of the nasal mucosa by spraying a dose of 0.5 mg/ml oximetazolin chlorid (Neseril®) into the nostrils. The latter recording provided an estimate of the anatomic resistance and the former an estimate of the physiological degree of swelling of the nasal mucosa.

Table 5 Error of method for measurements of airflow before and after nose drops

S.D. which represents the variance of the difference d between an initial value and a value obtained one month later is calculated from the formula $\Sigma(d_i - \bar{d})^2 / (N-1)$, where d_i is this difference for child i , \bar{d} is the mean of the differences and N is the number of double determinations.

S.D. is an estimate of the variance in the irregular error of individual determinations.

$\sigma^2 = \Sigma d^2 / N$ which is an estimate of the variance of the error in single measurements if there are no regular differences between measurements on different occasions.

\bar{d} is the variance in all the children in the study on the initial occasion.

Variable	Mean (controls)		Diff.	S.D.	$\frac{S.D.}{2}$	σ^2	S_{reg}^2	$\frac{S.D.}{2}$ in % of S_{reg}^2
	Initially	One month later						
A67 resp. A73 airflow before nose drops	40 18.79	18.65	0.14	16.72	8.36	8.20	27.41	30
A70 resp. A76 airflow after nose drops	30 25.56	26.97	-1.41	29.35	14.68	13.38	59.97	28

this is a cross-section rather than a longitudinal study the error of method should be seen in relation to the interindividual variation on a particular occasion. The size of the error in relation to the intraindividual variation between different occasions is therefore irrelevant here.

3 AIRFLOW VARIABLES

Airflow measurements in the same child at one month's interval were compared for the fifty controls for whom such data were obtained at 10, 15 and 0 mm H₂O. As measure

ments at these differential pressures display a very high intercorrelation ($r > 0.97$) only the error of method for airflow measurements at a differential pressure of 10 mm H₂O before (A67) and after (A70) nose drops will be considered here.

It will be seen from Table 5 that the error variance (%) for individual measurements is only slightly different from the irregular error in the individual determination ($S.D. / 2$). This indicates that there is no remarkable regular error between the airflow measurements obtained on the two occasions one month apart. Nor was any such difference expected, as one

Fig. 20 Correlations between measurements of airflow (lit./min.) before nose drops. (○) controls at the first (A67) and second (A73) examinations.

clinical measurements made on two occasions with an interval of one month

The double determinations were made on twenty children selected at random from the 162 children and concerned all the variables registered in the form of measurements. The sum of regular and irregular errors was calculated with the formula for the variance of

errors of method $\sigma^{*2} = \frac{\sum d^2}{2N}$ where d is the difference between two measurements and N is the number of double determinations

In order to assess the importance of the error of method the error variance (σ^{*2}) was studied in relation to the variance for all the 162 children (S^2_{162})

It was found that, with the exception of the variables listed in Table 4 the error variance amounted to less than 3% of the total variance for each variable

This means that for the majority of variables, the error of method is of little importance compared with the biological variation

In the case of variables for which the error variance is greater than 3% of the total variance there is a risk in simple correlation analyses that the size of the true correlations with other variables will be underestimated

The same applies to regression coefficients for these variables though here the error may involve an overestimation

From the last column in Table 4 it will be seen that no variable has an error variance of more than 10% of the total variance and that the largest error is for an angle measurement, namely A45 The angle between the occlusal and the nasion-sella lines

The error of method for the adenoid dentition skeleton and lip variables is only of secondary importance in the present context. Since

Table 4 Variables for which the variance of the error of method > 3% of the variance in all the children

σ^{*2} is an estimate of the variance of the error of method in mm for individual measurements on different occasions, determined from double determinations according to the formula $\sum d^2/2N$ where d is the difference between two occasions and N is the number of double determinations. S^2_{162} represents the variance in all the children in the study

clinical measurements made on two occasions with an interval of one month.

The double determinations were made on twenty children selected at random from the 162 children and concerned all the variables registered in the form of measurements. The sum of regular and irregular errors was calculated with the formula for the variance of errors of method $\sigma^{**} = \frac{\sum d^2}{2N}$ where d is the difference between two measurements and N is the number of double determinations.

In order to assess the importance of the error of method the error variance (σ^{**}) was studied in relation to the variance for all the 162 children (S^2_{162}).

It was found that, with the exception of the variables listed in Table 4 the error variance amounted to less than 3% of the total variance for each variable.

This means that for the majority of variables the error of method is of little importance compared with the biological variation.

In the case of variables for which the error variance is greater than 3% of the total variance there is a risk in simple correlation analyses that the size of the true correlations with other variables will be underestimated.

The same applies to regression coefficients for these variables though here the error may involve an overestimation.

From the last column in Table 4 it will be seen that no variable has an error variance of more than 10% of the total variance and that the largest error is for an angle measurement, namely A45. The angle between the occlusal and the nasion-sella lines.

The error of method for the adenoid, dentition, skeleton and lip variables is only of secondary importance in the present context. Since

Table 4 Variables for which the variance of the error of method $> 3\%$ of the variance in all the children

σ^{**} is an estimate of the variance of the error of method in mm for individual measurements on different occasions, determined from double determinations according to the formula $\sigma^{**} = d^2/2N$ where d is the difference between two occasions and N is the number of double determinations. S^2_{162} represents the variance in all the children in the study.

Table 6. Autocorrelations between the residuals when the children are arranged in time sequence

Residuals obtained as the difference between observed values and values predicted by the regression equation (these equations are given on p. 129). Dependent variables: airflow measured at a differential pressure of 10 mm H₂O before and after nose drops preoperatively (A67 and A70 respectively) and postoperatively (A73 and A76). r_{12} correlation between consecutive residuals r_{123} correlations between residuals one, two and three individuals apart respectively

Variable				
A67 Preop. airflow before nose drops	-0.03	0.04	0.13	-0.05
A70 Preop. airflow after nose drops	-0.04	0.12	0.09	-0.03
A73 Postop. airflow before nose drops	-0.03	-0.07	0.01	-0.06
A76 Postop. airflow after nose drops	0.10	-0.01	0.07	0.03

the mask may also have affected the swelling of the nasal mucous membrane. Errors of application and varying reactions to the instructions for airflow recordings presumably account for an essential part of the error of method.

(c) Calibration errors

The measuring apparatus was calibrated several times for pressure differences and flow during the course of the study. The calibrations proved to be almost constant. They were performed at the Laboratory of Physiological Climatology Akademiska Sjukhuset, Uppsala, in accordance with the procedure described by Dretner (1961).

Since the calibrations were undertaken only sporadically the regular error may have changed successively between calibrations. If this was the case, one would expect to find a positive correlation between the regular errors after two consecutive measurements. If one measurement displays a pronounced regular error it is thus to be expected that the next measurement will do the same.

This matter was investigated by calculating autocorrelations for the present data.

Although it is not possible, however, to measure the regular error directly one can calculate so-called residuals in the manner adopted in this study. Having obtained the differences between observed values and values predicted in accordance with the regression equation, the residuals are arranged in time sequence and autocorrelations are calculated

for consecutive residuals. A study of these correlations will show whether there is a consistent change in the regular errors.

As will be seen from Table 6, all the autocorrelations are low. Thus, no regular apparatus errors resulting in successive changes in the regular error between calibrations could be detected. The absence of autocorrelations between the residuals also indicates that there are no remarkable regular shifts as a result of the investigator's instructions and application of the apparatus for recording airflow.

(d) Actual changes in individuals between the first and second measurements

It is conceivable that the nasal mucosa changed between the first and second measurement owing to the start or end of an infection, a change in climate or the like. If such factors affected the nasal mucosa, their effect would be modified to some extent by nose drops. On the other hand, nose drops themselves may conceivably increase the variation from time to time to some extent.

According to Table 5 the error variances for variables A67 and A70 i.e. airflow before and after nose drops, bear almost the same relation to the variance for the total material, namely 30 and 28% respectively.

Since the error of method is only slightly reduced by nose drops, the change in nasal mucosa was probably small between the first and second recordings.

Fig. 1 Correlations between measurements of airflow (lit/min.) after nose drops in 69 controls at the first (A70) and second (A76) examinations.

month is too short an interval for any substantial biological changes in healthy subjects.

The variance of the irregular error in a single determination ($SD^2/2$) is large in relation to the mean as well as to the variance for all 162 individuals on the first occasion. This is also indicated by the correlations between airflow data in the controls on the first and second occasions for which the coefficients amounted to no more than 0.67 ($N=69$) and 0.75 ($N=69$) for airflow before and after nose drops respectively (see Figs 20 and 21).

Airflow is treated as a dependent variable in this study and consequently it is important to analyze the predictive value of different factors for the variance displayed by airflow. An important factor in this respect is the error of method which may comprise (a) apparatus errors, (b) errors of application and instruction (c) calibration errors and (d) actual changes in the individual between the first and second recordings.

(a) Apparatus errors

The error of method for the apparatus was analyzed in model tests in which the relation-

ship between flow and pressure difference was studied on rubber models of the nose reproduced from a post mortem impression of human nasal cavities and epipharynx (Drettner 1961). The error of method of the apparatus was calculated to ± 1.3 lit/min for an airflow of 39.8 lit/min measured at a differential pressure of 10 mm H₂O (Drettner 1961).

(b) Errors of application and instruction

The nose mask belonging to the apparatus was fitted in different ways according to the facial type of the child. As the same mask was used for all the children, it is possible that leakage occurred between the edge of the mask and the face. It is also conceivable that mechanical pressure from the mask around the nose altered the degree of swelling of the nasal mucous membrane in some cases. The recording sometimes took longer than usual if the child misunderstood the instructions and consequently failed to cooperate, for instance by sucking through the mouth tube or closing off communication between mouth and epipharynx with the tongue. In such cases, the accumulation of warm, moist air in the dead space of

The cineradiographs were analyzed in a viewer for 35 mm film (Arnoe Corp., Copenhagen) (Jensen, 1968) and tracings of single frames were made with the film projected on a translucent screen.

The position of the tongue during the three exposures in each individual was drawn on tracing paper and judged in relation to a line passing through the distal surface of the most distal upper molar perpendicular to a line through the contour of the floor of the nose (see Fig. 22). This assessment was made by the author together with an orthodontist well acquainted with cineradiographic analysis. Such tracings were made on three different occasions from each of the series of pictures from the three exposures.

The results show that the tongue is held considerably lower in mouth breathing than in nose breathing. The tongue was held highest during the second exposure (nose breathing

with the mouth open). This is natural since, with the mouth open, the tongue is held against the soft palate to achieve breathing through the nose alone. It is particularly noteworthy that the position of the tongue remained unchanged throughout each of the three exposures with the exception of two cases in which it moved somewhat during the first exposure (nose breathing with the lips closed).

Exact measurements of tongue position during the exposures were not attempted in view of the difficulty of determining whether observations during forced mouth breathing also apply to persons who breath through the mouth on account of nasal obstruction.

The good stability of tongue position during 5 sec cineradiography strengthens the reliability of assessments of tongue position in nose breathers and mouth breathers simply by studying lateral radiographs.

Fig. 2 Cineradiographic photographs and tracings of tongue position during (a) nose breathing with mouth closed, (b) nose breathing with mouth open, and (c) mouth breathing.

4 VARIABLES FOR TONGUE POSITION

Double determinations of tongue position in relation to the hard and soft palates were made on lateral radiographs in the same way as for the adenoid skeleton and lip variables. The error variance amounted to less than 5% of the total variance.

In order to assess how stable the position of the tongue is between lateral radiographs taken at intervals of a few seconds, tongue position was also filmed cineradiographically for 5 sec. This was done with the type of film and apparatus described by Jensen (1968). The

films were taken at a frequency of 24 frames per second.

Cineradiographs were taken in 8 students with normal occlusion, three exposures lasting 5 sec each being made in each individual.

During the first exposure the subject breathed through the nose, held the lips closed and kept the lower jaw in the rest position.

During the second exposure, conditions were the same as for the first except that the mouth was kept open.

During the third exposure the subject breathed through the mouth alone with the lower jaw in a resting position.

performed with x and z as regressors and using the equation $y = a + bx + cz$. It will be found that the coefficient in front of x i.e. $b = 0.000$. This regression coefficient expresses the effect of variable x on y when allowance is made for z . In the present case, the regression coefficient indicates that x has no effect.

Briefly then, a simple correlation or regression analysis does not always give the same result as a partial or a multiple regression analysis.

Furthermore, it should be noted that a regression coefficient must also be interpreted in the light of the other variables included in the regression analysis. In other words, an analysis will depend upon which variables are included. Consequently the selection of regressors is of major importance. In particular one should try to avoid including regressors that are causally influenced by the regressand. The regressors which occur in the present study can thus be regarded either as conceivable causes of the regressand or as symptoms of an underlying variable with a conceivable causal effect on the regressand.

In the case of certain regressands, the number of possible regressors exceeded the capacity of the computer programme. In such cases the regressors that did not show a significant simple correlation with the regressand were excluded and in this way the number of regressors in the regression analyses never exceeded 68.

The regression analyses that are described in greater detail have only a few regressors for which partial correlation and regression coefficients are reported. This is because only regressors significant at the 5% level have been included.

Stepwise regression analyses have been performed. This means that the regressor with the strongest positive or negative correlation with the regressand is introduced first, after which one introduces the regressor that shows the strongest partial correlation to the regressand with allowance for the first regressor and so on.

A list of the sequence in which the regressors were introduced is given in connection with the regression analyses. With this stepwise procedure the analysis is discontinued when the regressor to be introduced next does not reach the requisite level of significance.

R^2 (the square of the multiple correlation coefficient) indicates how large a part of the regressand's variance can be attributed to the regressors (see Appendix, p 128).

If $R^2 = 0$ nothing of the variance can be attributed to the regressors, while if $R^2 = 1$ then all the variability is attributable to the regressors. Obviously it is desirable to have a high value for R^2 . In this study values of $R^2 < 0.30$ are regarded as weak, while $R^2 > 0.50$ is considered satisfactory.

Weak values of R^2 may be a consequence of a large error of method for the regressand (cf. the discussion with A67 and A70 as regressands, pp 88, 89). They may also indicate that essential variables have not been registered. No additional variables of importance were discovered, however, in the course of a study of large residuals.

Another reason for low values of R^2 may be that several measurements are lacking for certain variables, particularly those connected with the dentition and airflow (in the case of dentition variables, children who were changing from deciduous to permanent teeth, in the case of airflow variables, children who had difficulty in managing the nasal airflow apparatus).

Finally it should be mentioned that R^2 is sometimes low when only regressors with significant correlation coefficients are included but rises substantially when other regressors are taken into account.

Concerning values of $R^2 > 0.50$, it should be noted that these may be relatively high as the regressors involved serve as indicators of the same condition as the regressand.

If only two variables x and y are studied, then $r^2(xy) = R^2$. In the above example where $r = -0.30$ R^2 amounts to only 0.09 i.e. a very low determinative value even though the correlation coefficient shows a high level of

Methods for analyzing relationships

The relationships between variables have been studied with the aid of simple correlation analysis and multiple regression analysis. The formulas employed are reported in the appendix Statistical methods. The following is a brief account of what these methods of analysis involve and why and how they were performed.

Let us start with a *simple correlation* between the variables x and y . This gives an indication of the relationship between x and y without taking other variables into account. In order to see what happens when the correlations of other variables to x and y are also considered, one can perform *partial correlation analysis* or *multiple regression analysis*.

The value of *partial correlation analysis* is illustrated by the following example, in which three variables— x , y and z —symbolize airflow (A67), mouth breathing (A15) and size of adenoids (A20) respectively.

Between x and y the correlation coefficient $r = -0.30$ which is highly significant ($P < 0.001$). This correlation tells us that mode of breathing and airflow are related and that airflow is lower on the average for mouth breathers than nose breathers.

We can then investigate whether this relationship is entirely due to adenoids obstructing the airflow and consequently increasing the propensity to breathe through the mouth. The correlation coefficient between x and z is $r = -0.45$ suggesting that airflow is inhibited by size of adenoids, while the correlation between y and z is $r = 0.66$ indicating that mouth breathing is more common among the children whose adenoids are large.

Thus we have found that $r(xy) = -0.30$, $r(xz) = -0.45$ and $r(yz) = 0.66$. The relationship between two variables when a third var-

iable is kept constant is expressed by the *partial correlation*, which is calculated according to the formula

$$r(xy.z) = \frac{r(xy) - r(xz) \cdot r(yz)}{\sqrt{(1 - r^2(xz))(1 - r^2(yz))}}$$

Substituting our correlations in this formula gives $r(xy.z) = -0.01$. This implies that the relationship between mouth breathing and airflow is entirely attributable to these variables relationship with size of adenoids. In other words, if allowance is made for size of adenoids the relationship between mode of breathing and airflow as measured by the correlation coefficient is almost equal to 0.

In this example it is more interesting to learn that the relationship between x and z is entirely attributable to z , than simply to learn that x and y display a negative correlation.

Partial correlation analysis can be extended to cover more than one variable in addition to x and y . Thus one can study the relationship between x and z while making allowance for the k variables v_1, v_2, \dots, v_k . It is *partial correlation coefficients of this type* that are reported in the tables for the regression analyses.

The change in the strength of a relationship that can be detected by extending a simple correlation to a partial correlation has its counterpart in an extension from *simple regression* to *multiple regression*. Suppose that in a regression analysis of the present data, $y = A15$ (Mouth breathing) is chosen as the regressand and $x = A67$ (Airflow) as the regressor. Using the equation $y = A + Bx$ one obtains the regression coefficient $B = -0.028$ which differs significantly from 0 ($P < 0.001$).

If instead a multiple regression analysis is

Results of comparisons between the adenoidectomy and control groups and of simple correlation analyses

The first part of this chapter presents in separate sections the variable groups for anamnesis, dentition, adenoids, airflow obstruction & lips and tongue position respectively. The definitions of the variables featured in the tables will be clear from the list of variables in Table 1 pp 13-15. In each section percentages, means and standard deviations are reported separately for each of the three control groups (classified by radiographic size of adenoids) and the two adenoidectomy groups (classified by the indication for operation, recurrent otitis media or nasal obstruction). The standard deviations are of interest, in that, for instance, they indicate the degree of overlapping between the groups.

The other part of the chapter is devoted to simple correlations between variables belonging to the same group as well as between variables belonging to different variable groups. Correlation coefficients are shown specifically in the tables only if they are significant at the 1% level. Furthermore, in view of the strong intercorrelations displayed by the airflow measurements at differential pressures of 10, 15 and 20 mm H₂O ($r > 0.97$) only airflow at 10 mm H₂O has been included in the tables of correlations between the airflow variables and other variables.

In order to avoid making the analysis of results unnecessarily repetitive, the presentation in this chapter is purely descriptive. Discussions of the results will be found in the next chapter together with the presentation of results from the multiple regression analyses.

COMPARISONS BETWEEN THE ADENOIDECTOMY AND CONTROL GROUPS

Anamnesis and clinical status variables

The percentage incidences for certain anamnestic variables and certain clinical status variables defined in accordance with Table 1 are presented in Table 7.

Only one definition has been altered from Table 1 namely concerning variable A04 Mode of breathing, in that the category "breathing through both nose and mouth" has been dropped. The children who reported that they breathed in this way are included in Table 7 with those who breath through the mouth, which clarifies the criteria for nose breathing.

Standard deviations can be calculated from the data provided in the table using the formula

$$\sqrt{\frac{n}{n-1}p(100-p)}$$

where p is the observed percentage.

For all variables the number of observations amounts to 162. The occurrence of significant differences at the 1% or 0.1% level between any pair of groups is noted in the last column of the table. The group with the largest percentage has been compared with the group or groups with smaller percentages.

Groups 1, 2 and 3 comprise unoperated controls, while the adenoidectomy children make up groups 4 and 5.

From Table 7 it will be seen that the percentage distribution by sex is much the same

significance ($P < 0.001$) The example also shows that an analysis of the significance of the correlation coefficients should include information on the coefficient of determination

A very large number of variables has been included in the present study (cf Table 1) Many of them were not expected to display particularly strong correlations with the regressands investigated namely adenoid, airflow and dentition variables They were simply included as a means of exposing any unexpected correlations This *exploratory* approach was adopted since there does not appear to be any means of specifying which set of regressors will give rise to values of $R^2 > 0.50$

This exploratory approach however involves a risk of obtaining artefact significant coef

ficients To guard against this, a comparison has been made between the number of significant analyses observed and expected at the 5% 1% and 0.1% levels (see Table 53, p. 115)

Data processing

All calculations in this study have been performed on the UDAC (Uppsala) computer CDC 3600

The Interest Programme at UDAC was employed in the calculations for *simple correlation analyses means standard deviations, etc.*

The *regression analysis* programme used in the processing of data as described above was taken from Thorner (1966)

in all groups with the exception of group 3 which however consists of only 11 children. It will also be seen that the sex distribution in the total material is 40% girls and 60% boys (by definition, girl = 1 and boy = 0 cf. Table 1).

The percentages for almost all the variables in Table 7 for the unoperated children (i.e. for groups 1, 2 and 3 combined) are considerably lower than for the adenoidectomy children (i.e. groups 4 and 5 combined). Variable A10, Prolonged finger-sucker is an exception, group 5 having the smallest percentage and group 3 the largest.

Group 1 has very low percentages for the majority of variables, though it is worth noting that even in this group there are children who sleep with their mouth open (A05 8%) or who otherwise have their mouth open (A12, 5%).

Group 2 displays the same tendencies as group 1.

The percentages for group 3 Unoperated children with large adenoids, are considerably higher than in group 1 for several variables.

The adenoidectomy children (groups 4 and 5) display a high incidence of mouth breathing, the figures for variables A04 and A15 being 90-95% in group 5 and 57-71% in group 4.

The different percentages for the unoperated and the adenoidectomy groups can hardly be explained by discrepancies in the procedure for investigating their anamneses.

When assessing the anamnesis of all the adenoidectomy children, the author had access to the otologist's report with the same anamnestic data (see Table 2, p. 77). In the case of the unoperated controls, on the other hand, the anamnesis was assessed entirely independently by an otologist and the author (see Table 3 p. 28). If the two assessments did not agree (see Tables 2 and 3 pp. 27-28), the author's was adopted.

The data on clinical states represented by variables A12-15 are derived from examinations by the author while those represented by

variables A16-19 have been provided by an otologist. The unoperated controls were assessed by one of two otologists and the adenoidectomy children by one of six otologists.

There is a large number of significant differences between groups, in the first place between groups 4 and 5 on the one hand and groups 1, 2 and 3 on the other. In the case of variables A08, A11, A15 and A16, the inter-group differences are a consequence of the group definitions (see p. 12).

Concerning mode of breathing (A04, A15) mouth in sleep (A05), recurrent infections in the ear, nose and throat (A06) open or closed mouth (A12) and enlarged adenoids (A16) the differences between groups 4 and 5 in relation to groups 1, 2 and 3 are in line with what one would expect, viz. that the incidences of mouth breathers, of recurrent infections in the ear, nose and throat and of enlarged adenoids are highest in the adenoidectomy groups.

Furthermore, one might expect that for the variables with differences between adenoidectomy and control groups, group 3 would occupy an intermediate position between groups 4 and 5 and groups 1 and 2. This appears to be the case for mode of breathing (A04), open or closed mouth (A12) obstructed nose breathing (A13-14) and enlarged adenoids (A16). On the other hand, group 3 has a higher percentage—though not significantly higher—than any other group for number of siblings with ear, nose and throat diseases (A09) and incidence of prolonged finger suckers (A10). Neither does group 3 differ significantly from group 1 and group 2 in any of the other variables listed in Table 7. Nor are there any significant differences between groups 1 and 2.

Group 5 has significantly higher percentages than group 4 ($P < 0.01$) for mouth in sleep (A05), open or closed mouth (A12), obstructed nose breathing (A13-14) and mouth breathing (A15). Obstructed nose breathing is particularly frequent in group 5. These differences are to be expected since nasal obstruction was the indication for adenoidectomy and served as the basis for the definition of group 5.

Table 7 Percentage frequency of variables concerning anamnesis and clinical status in the five groups of children

A total of 162 observations were obtained for all variables. Significant differences ($P < 0.01$) between the groups are listed in the last column (the group with the highest percentage has been compared with the group or groups that had smaller percentages)

	S.E.	0.13	0.22	0.33	0.38	1.56 0.20	

The significant differences between groups 5 and 1 in respect of large tonsils (A17) and swollen nasal mucosa (A18) are no doubt connected with the high incidence of obstructed nose breathing (A13-14) and recurrent infections in the ear nose and throat (A06) noted for group 5

A particularly noteworthy significant difference is that between groups 5 and 1 concerning variable A09 Number of siblings with ear nose and throat diseases

The mean ages of the five groups, expressed by year of birth are shown in Table 8

The children in control group 3 i.e. children with large radiographic size of adenoids but no clinical discomfort, have a significantly younger mean age than those in groups 1 and 5 i.e. controls without adenoids and adenoidectomy children with obstructed nose breathing respectively

Summary

The results presented in Table 7 appear to fully justify the present classification of the children into five groups. There is a large number of significant intergroup differences particularly between the control groups (1, 2 and 3) and the adenoidectomy groups (4 and 5). Control group 3 which comprises children with large radiographic size of adenoids on the posterior wall of nasopharynx but no clinical discomfort occupies an intermediate position between the other two control groups and the

adenoidectomy groups in the case of the variables connected with mode of breathing. With the exception of age which is lower for group 3 than group 1 no significant differences have been found between the three control groups. Between the adenoidectomy groups (4 and 5) on the other hand there are significant differences for mouth open in sleep open or closed mouth, nasal obstruction (left and right) mouth breathing and the variable for size of tonsils. The children who underwent adenoidectomy for nasal obstruction included a higher proportion of mouth breathers and large tonsils than those who underwent adenoidectomy on account of recurrent otitis media. This supports obstructed nose breathing as the otologist's indication for adenoidectomy

Dentition variables

Data concerning dentition variables are presented in Table 9 (for definitions see Table 1)

As will be seen from the last column of Table 9 there are several significant differences between the group means. In the case of several dentition variables the largest differences are mostly between the means for groups 1 and 5. This is particularly noteworthy since as will be seen from Table 7 these two groups also differ most in respect of mode of breathing (A04, 05, 15) and nasal obstruction (A13, 14, 16)

Furthermore the means for several denti

tion variables in group 3 differ significantly from the corresponding means in groups 1 and 5. Here, however, it should be remembered that the children in group 3 have a significantly younger mean age than those in groups 1 and 5 (cf. Table 8).

Group 5 differs significantly from the other groups in respect of the mean for variable A48, i.e. inclination of the lower incisors in relation to the mandibular line. Group 5 has the lowest mean, indicating that on the average the lower incisors are more retroclined in these children.

In the case of variable A47, i.e. the mutual inclination of the lower and upper incisors, group 5 has a significantly higher mean than groups 1 and 2. This is partly a consequence of the circumstance that group 5 also has a significantly lower mean than group 1 for variable A46, i.e. inclination of the upper incisors in relation to the nasion-sella line. Thus the upper incisors are more retroclined on the average in the children belonging to group 5.

Group 5 has a significantly higher mean than group 1 for variable A45, i.e. angle between occlusal and nasion-sella lines. Group 2 also differs significantly from group 1 in this respect.

Group 5 has a significantly higher mean than group 4 for variable A44, i.e. angle between occlusal and mandibular lines. The means for variables A49, Upper arch width between first molars, and A54, Lower arch length, are significantly smaller for group 5 than for group 1. On the other hand, group 5 has significantly higher means than group 1 for variables A59, Crossbite, and A63, Index for lower and upper arch widths between first molars. Group 3 also has a significantly higher mean than group 1 in the case of variable A63.

In the case of the related variables A53, Length of upper arch, and A65, Index for length and breadth of upper arch, group 3 has significantly lower means than groups 1, 4 and 5.

Group 3 also has a significantly lower mean than groups 1, 2 and 4 for variable A56, Over bite.

Summary

The results in Table 9 show that the children in adenoidectomy group 5 tend to have retroclined upper and lower incisors, a narrow upper arch, a short lower arch, a high incidence of crossbite and wide angles between the occlusal line on the one hand and the nasion-sella and mandibular lines on the other. Otherwise the significant differences in Table 9 refer to comparisons between the controls in group 3 and other groups. On the average the children in group 3 appear to have a short upper arch and a small overbite. It should be noted, however, that the children in group 3 have a significantly younger mean age than the controls in group 1 and the children in adenoidectomy group 5.

Adenoid variables

Data concerning adenoid variables are presented in Table 10 (for definitions see Table 1). Variables connected with the postoperative size of adenoids (A21, 27, 28, 30, 31, 33, 34, 36, 37, 39 and 41) were not of course relevant in the case of the controls (groups 1, 2 and 3).

There is a large number of significant differences between the group means. In the case of several adenoid variables the largest differences are mostly between group 1 and the other groups. This is in accordance with the group definitions. The large significant differences between control groups 1 and 2 on the one hand and the adenoidectomy groups 4 and 5 on the other for size of adenoids (variables A20, 6, 9, 32, 35, 38 and 40) were also expected and agree with the definitions of controls and subjects. On the other hand, the high means for these variables in group 3 were unexpected since these children had been included as controls because the clinical assessment showed them to be free of discomfort. These means in group 3 are in fact significantly different from those in group 1. Concerning these variables, moreover, it is only for A38 that the means in groups 3 and 5 are significantly different, while no significant differences were

Table 10 Mean (M) and standard deviation (S D) of adenoid variables for the children in the five groups

The number of children (n) is indicated for variables with a drop-out of more than 10% i. e. if $N < 145$. Significant differences ($P < 0.01$) are listed in the last column (the group with the higher mean has been compared with the group or groups with lower means)

obtained between groups 3 and 4. Size of adenoids measured radiographically is thus the same on the average for the children in groups 3 and 4 and considerably larger than for those in group 1.

A significant difference of particular interest is that between groups 4 and 5 for variable A20 i.e. size of adenoids in relation to the nasopharynx. The children who were adenoid ectomized for obstructed nose breathing thus appear to have a larger mean size of adenoids than those who underwent the operation on account of recurrent otitis media.

The significant differences between groups 4 and 5 for variables A22 and A24 i.e. obstructed nose breathing and recurrent otitis media respectively as indications for adenoid ectomy are to be regarded as a consequence of the definitions of these groups.

Summary

As shown by Table 10 the means for size of adenoids display a large number of significant intergroup differences. The differences between the control groups (1, 2 and 3) were expected and agree with the definitions of these groups. The existence of group 3 with its high means is unexpected however as the clinical assessment of these children showed them to be free of discomfort. The significant differences in means for size of adenoids between the adenoidectomy groups (4 and 5) is particularly interesting. The children adenoidectomized for obstructed nose breathing appear to have had larger adenoids on the average than those who underwent the operation on account of recurrent otitis media.

Airflow variables

Data concerning airflow variables are presented in Table 11 (for definitions see Table 1). It should be noted that variables A67-72 concern nasal airflow at the first examination i.e. immediately before adenoidectomy in the case of groups 4 and 5 while variables A73-78 refer to the examination one month later i.e.

1 month after adenoidectomy in the case of groups 4 and 5. Furthermore variables A67-69 and A73-75 concern nasal airflow before nose drops, whereas A70-72 and A76-78 concern nasal airflow after nose drops.

Variables A67, A70, A73 and A76 express nasal airflow measured at a differential pressure of 10 mm H₂O while the corresponding measurements at a differential pressure of 15 mm H₂O are expressed by A68, A71, A74 and A77 and those at 20 mm H₂O by A69, A72, A75 and A78.

As will be seen from Table 11 nasal airflow measurements were obtained for between 8 and 10 children in group 3 which is considerably fewer than in any of the other groups.

The very low means for nasal airflow in group 3 (see Table 11) are particularly noteworthy. According to the clinical assessment, adenoidectomy was not indicated in these children who were therefore accepted as controls. The radiographic assessment however showed that group 3 had large adenoids in relation to the bony nasopharynx (cf variables A20, A32 and A35 in Table 10). The consistently low means for nasal airflow in group 3 appear to support the radiographic assessment of the size of adenoids in these children.

Groups 1 and 2 were also classified according to the radiographic assessment of size of adenoids whereas groups 4 and 5 were obtained from the indication for adenoidectomy: recurrent otitis media and obstructed nose breathing respectively.

There is a large number of significant intergroup differences. As far as the first examination is concerned, these differences mostly apply to mean airflow before nose drops (A67-68) between groups 1 and 2 on the one hand and groups 3 and 5 on the other. Furthermore the means for variables A67-69 display significant differences between groups 4 and 3. After nose drops at the first examination variables A70-71 (corresponding to A67-68 before nose drops) show significant differences only between group 1 and groups 2, 3 and 5. Variable A72 i.e. airflow measured at 20 mm

Table 11 *Mean (M) and standard deviation (S.D.) of airflow variables for the children in the five groups*Significant differences ($P < 0.01$) are listed in the last column (the group with the higher mean has been compared with the group or groups with lower means)

H₂O after nose drops (corresponding to A69 before nose drops) shows significant differences only between group 1 and groups 3 and 5.

None of the means in group 4 differ from those in groups 1 and 2 for variables A67-72 i.e. airflow at the first examination before as well as after nose drops. This is remarkable considering the differences found in size of adenoids between group 4 and groups 1 and 2 (cf variables A20, A32 and A35 in Table 10).

Concerning the second examination, i.e. 1 month after adenoidectomy in the case of groups 4 and 5 the significant differences for airflow before nose drops (A73-75) mostly involve groups 1 and 4 on the one hand and group 3 on the other. These differences were also found at the first examination (variables A67-69).

The significant differences between groups 1 and 5 before adenoidectomy and before nose drops (A67-69) were repeated before nose drops after adenoidectomy only in the case of airflow measured at a differential pressure of 20 mm H₂O (A75). Airflow after nose drops at the second examination (1 month after adenoidectomy for groups 4 and 5 variables A76-78) is significantly different not only between group 1 and groups 3 and 5 as it was at the first examination (A70-72) but also between group 5 and group 3.

It appears from Table 11 that nasal airflow is increased after adenoidectomy. However 1 month after the operation the mean values for the adenoidectomy children had not reached the same level as those for group 1 i.e. children with no clinical or radiographic signs of adenoids on the posterior wall of the nasopharynx.

Group 3 which comprises children with no clinical indications for adenoidectomy but large adenoids according to the radiographic assessment, displays relatively similar means for airflow at the first and second examinations (compare A67-72 with A73-78).

Since the largest size of adenoids at the first examination is found in groups 3 and 5 (cf A20, A32 and A35 in Table 10) these groups

can be expected to display similar means for airflow at the first examination. This is confirmed in Table 11 by the good agreement between groups 3 and 5 in mean airflow at the first examination after nose drops (A70-72). At the second examination, i.e. 1 month after adenoidectomy in group 5 (A76-78), mean airflow after nose drops is considerably higher in group 5 than in group 3.

A picture of the percentage distribution of nasal airflow is provided by Fig. 23 a-h, in which the controls in group 1 are compared with the adenoidectomy children (groups 4 and 5). It will be seen that before adenoidectomy groups 4 and 5 have a considerably lower airflow than group 1 and that the differences are not as pronounced after the operation. These results agree with the findings in Table 11.

Concerning airflow before adenoidectomy however it will be seen from Fig. 23 a-h that there is a certain amount of overlapping. Thus, Fig. 23 a shows that 51% of the children in group 1 have an airflow of more than 20 l/min but only 7% of group 5 and that only 9% of group 1 had an airflow of less than 15 l/min compared with 48% of group 5. Overlapping is least pronounced in Figs. 23 a and 23 b. After adenoidectomy the degree of overlapping is notably greater and there are no significant differences between the means.

Summary

From Table 11 it can be seen that nasal airflow at a differential pressure of 10 mm H₂O varies partly on account of enlarged adenoids. The table shows that airflow is increased after adenoidectomy. One month after the operation, however, the mean airflow in the adenoid-

Fig. 23 Airflow diagrams, (a and e) before nose drops and before adenoidectomy, (b and f) after nose drops before adenoidectomy, (c and g) before nose drops after adenoidectomy, (d and h) after nose drops after adenoidectomy. a, b, c and d compare the children in groups 1 and 5, e, f, g and h compare those in groups 1 and 4. The plots indicate the percentage of children in the various airflow classes and thus give the distribution. Each class has a range of 5 l/min and the plots have been located in the centre of the class.

H₂O after nose drops (corresponding to A69 before nose drops) shows significant differences only between group 1 and groups 3 and 5.

None of the means in group 4 differ from those in groups 1 and 2 for variables A67-72, i.e. airflow at the first examination before as well as after nose drops. This is remarkable considering the differences found in size of adenoids between group 4 and groups 1 and 2 (cf. variables A20, A32 and A35 in Table 10).

Concerning the second examination i.e. 1 month after adenoidectomy in the case of groups 4 and 5 the significant differences for airflow before nose drops (A73-75) mostly involve groups 1 and 4 on the one hand and group 3 on the other. These differences were also found at the first examination (variables A67-69).

The significant differences between groups 1 and 5 before adenoidectomy and before nose drops (A67-69) were repeated before nose drops after adenoidectomy only in the case of airflow measured at a differential pressure of 20 mm H₂O (A75). Airflow after nose drops at the second examination (1 month after adenoidectomy for groups 4 and 5 variables A76-78) is significantly different not only between group 1 and groups 3 and 5 as it was at the first examination (A70-72) but also between group 5 and group 3.

It appears from Table 11 that nasal airflow is increased after adenoidectomy. However 1 month after the operation the mean values for the adenoidectomy children had not reached the same level as those for group 1 i.e. children with no clinical or radiographic signs of adenoids on the posterior wall of the nasopharynx.

Group 3 which comprises children with no clinical indications for adenoidectomy but large adenoids according to the radiographic assessment, displays relatively similar means for airflow at the first and second examinations (compare A67-72 with A73-78).

Since the largest size of adenoids at the first examination is found in groups 3 and 5 (cf. A20, A32 and A35 in Table 10) these groups

can be expected to display similar means for airflow at the first examination. This is confirmed in Table 11 by the good agreement between groups 3 and 5 in mean airflow at the first examination after nose drops (A70-72). At the second examination i.e. 1 month after adenoidectomy in group 5 (A76-78) mean airflow after nose drops is considerably higher in group 5 than in group 3.

A picture of the percentage distribution of nasal airflow is provided by Fig. 23 a-h in which the controls in group 1 are compared with the adenoidectomy children (groups 4 and 5). It will be seen that before adenoidectomy groups 4 and 5 have a considerably lower airflow than group 1 and that the differences are not as pronounced after the operation. These results agree with the findings in Table 11.

Concerning airflow before adenoidectomy however it will be seen from Fig. 23 a-h that there is a certain amount of overlapping. Thus, Fig. 23 a shows that 51% of the children in group 1 have an airflow of more than 20 lit/min but only 7% of group 5 and that only 9% of group 1 had an airflow of less than 15 lit/min compared with 48% of group 5. Overlapping is least pronounced in Figs. 23 a and 23 b. After adenoidectomy the degree of overlapping is notably greater and there are no significant differences between the means.

Summary

From Table 11 it can be seen that nasal airflow at a differential pressure of 10 mm H₂O varies partly on account of enlarged adenoids. The table shows that airflow is increased after adenoidectomy. One month after the operation however the mean airflow in the adenoid-

75 POSTOP AIRFLOW AFTER NOSE DROPS

H₂O after nose drops (corresponding to A69 before nose drops) shows significant differences only between group 1 and groups 3 and 5.

None of the means in group 4 differ from those in groups 1 and 2 for variables A67-72, i.e. airflow at the first examination before as well as after nose drops. This is remarkable considering the differences found in size of adenoids between group 4 and groups 1 and 2 (cf variables A20, A32 and A35 in Table 10).

Concerning the second examination i.e. 1 month after adenoidectomy in the case of groups 4 and 5 the significant differences for airflow before nose drops (A73-75) mostly involve groups 1 and 4 on the one hand and group 3 on the other. These differences were also found at the first examination (variables A67-69).

The significant differences between groups 1 and 5 before adenoidectomy and before nose drops (A67-69) were repeated before nose drops after adenoidectomy only in the case of airflow measured at a differential pressure of 20 mm H₂O (A75). Airflow after nose drops at the second examination (1 month after adenoidectomy for groups 4 and 5 variables A76-78) is significantly different not only between group 1 and groups 3 and 5 as it was at the first examination (A70-72) but also between group 5 and group 3.

It appears from Table 11 that nasal airflow is increased after adenoidectomy. However 1 month after the operation the mean values for the adenoidectomy children had not reached the same level as those for group 1 i.e. children with no clinical or radiographic signs of adenoids on the posterior wall of the nasopharynx.

Group 3 which comprises children with no clinical indications for adenoidectomy but large adenoids according to the radiographic assessment, displays relatively similar means for airflow at the first and second examinations (compare A67-72 with A73-78).

Since the largest size of adenoids at the first examination is found in groups 3 and 5 (cf A20, A32 and A35 in Table 10) these groups

can be expected to display similar means for airflow at the first examination. This is confirmed in Table 11 by the good agreement between groups 3 and 5 in mean airflow at the first examination after nose drops (A70-72). At the second examination, i.e. 1 month after adenoidectomy in group 5 (A76-78) mean airflow after nose drops is considerably higher in group 5 than in group 3.

A picture of the percentage distribution of nasal airflow is provided by Fig. 23 a-h in which the controls in group 1 are compared with the adenoidectomy children (groups 4 and 5). It will be seen that before adenoidectomy groups 4 and 5 have a considerably lower airflow than group 1 and that the differences are not as pronounced after the operation. These results agree with the findings in Table 11.

Concerning airflow before adenoidectomy however it will be seen from Fig. 23 a-h that there is a certain amount of overlapping. Thus, Fig. 23 a shows that 51% of the children in group 1 have an airflow of more than 20 lit/min but only 7% of group 5 and that only 9% of group 1 had an airflow of less than 15 lit/min compared with 48% of group 5. Overlapping is least pronounced in Figs. 23 a and 23 b. After adenoidectomy the degree of overlapping is notably greater and there are no significant differences between the means.

Summary

From Table 11 it can be seen that nasal airflow at a differential pressure of 10 mm H₂O varies partly on account of enlarged adenoids. The table shows that airflow is increased after adenoidectomy. One month after the operation however the mean airflow in the adenoid-

Fig. 23 Airflow diagrams, (a and c) before nose drops and before adenoidectomy (b and d) after nose drops before adenoidectomy (e and g) before nose drops after adenoidectomy (f and h) after nose drops after adenoidectomy. a, b, e and f compare the children in groups 1 and 5; c, d, g and h compare those in groups 1 and 4. The plots indicate the percentage of children in the various airflow classes and thus give the distribution. Each class has a range of 5 lit/min and the plots have been located in the centre of the class.

ectomy children had not reached the level recorded in children with no clinical or radiographic signs of adenoids. The number of significant intergroup differences in respect of mean airflow values seems to fully justify the division of the material into these groups.

Skeleton and lip variables

The results for skeleton and lip variables are shown in Table 1 (for definitions see Table 1).

There are several significant differences between the means for the various groups.

Total face height (A81-A88) is significantly larger in group 5 than in groups 1, 3 and 4.

Anterior upper face height (A89) is significantly larger in groups 1 and 5 than in group 3. Anterior lower face height (A90) is significantly larger in group 5 than in groups 2, 3 and 4.

Nose width (A82) is significantly larger in groups 1 and 4 than in group 3.

The sagittal depth of the bony nasopharynx (A92) is significantly smaller in group 5 than in group 1. The volume of the bony nasopharynx (A101) is significantly greater in group 1 than in group 2. The height of the bony nasopharynx (A93) is significantly greater in group 5 than in group 3.

Posterior upper face height (A94-A95) is significantly smaller in group 3 than in groups 1, 4 and 5.

Face width (A98) is significantly greater in group 1 than in group 3.

The posterior choanal aperture (A100) is significantly wider in group 1 than in group 2. The angles s-a-m and s-a-sm (A102 and A103 respectively) are significantly wider in group 1 than in groups 2 and 5.

The angle between the mandibular line and the nasion-sella line (A106) is significantly

ectomy children had not reached the level recorded in children with no clinical or radiographic signs of adenoids. The number of significant intergroup differences in respect of mean airflow values seems to fully justify the division of the material into these groups.

Skeleton and lip variables

The results for skeleton and lip variables are shown in Table 12 (for definitions see Table 1).

There are several significant differences between the means for the various groups.

Total face height (A81-A88) is significantly larger in group 5 than in groups 2, 3 and 4.

Anterior upper face height (A89) is significantly larger in groups 1 and 5 than in group 3. Anterior lower face height (A90) is significantly larger in group 5 than in groups 2, 3 and 4.

Nose width (A82) is significantly larger in groups 1 and 4 than in group 3.

The sagittal depth of the bony nasopharynx (A92) is significantly smaller in group 5 than in group 1. The volume of the bony nasopharynx (A101) is significantly greater in group 1 than in group 2. The height of the bony nasopharynx (A93) is significantly greater in group 5 than in group 3.

Posterior upper face height (A94-A95) is significantly smaller in group 3 than in groups 1, 4 and 5.

Face width (A98) is significantly greater in group 1 than in group 3.

The posterior choanal aperture (A100) is significantly wider in group 1 than in group 3. The angles s-n-as and s-n-am (A102 and A103 respectively) are significantly wider in group 1 than in groups 2 and 5.

The angle between the mandibular line and the nasion-sella line (A106) is significantly

bles. This is because variables A129-131 were measured only (a) in the controls in group 1 whose size of adenoids (A32) was less than the mean for this group (73.64%) and (b) in the children in group 5 i.e. adenoidectomy for obstructed nose breathing, whose value for the same variable was greater than the mean for this group (91.19%).

Significant differences between the means for groups 1 and 5 are shown for the shortest distance between the tongue and pterygomaxillary (A129) as well as for the shortest distance between the tongue and the midpoint of the soft palate (A131).

Summary

Table 13 indicates that the children in this study who underwent adenoidectomy for obstructed nose breathing appear to have held the tongue in a lower position than the children whose nasal passages were unobstructed.

SIMPLE CORRELATION ANALYSES

Correlations between variables concerning anamnesis and clinical status

Simple correlations between all pairs of anamnesis and clinical status variables except A11

and A12 are presented in Table 14. Variable A11 Previous orthodontic therapy is not included—either here or subsequently—because it was found that only three children in the entire material had previously received such therapy. Variable A12, Open or closed mouth, was excluded as it correlates strongly with A15 Mouth breathing. For definitions of the variables see Table 1.

As will be seen, a large number of correlations in Table 14 are significant at the 1% level, i.e. the correlation coefficient $|r| \geq 0.20$.

Furthermore, all correlations between variables A04-06, A13-15 are significant at the 0.1% level, i.e. $|r| \geq 0.40$. With the exception of A06, these variables have to do with the mode of breathing and the presence of nasal obstruction. The significant correlations between these variables and A16 Enlarged adenoids, support the current opinion that size of adenoids strongly influences the mode of breathing and contributes to recurrent infections in the ear nose and throat.

Previous adenoidectomy (A08) is significantly correlated to large tonsils (A17), certain variables concerning mode of breathing (A04-05) and recurrent infections in the ear nose and throat (A06).

The correlations for A17 Large tonsils, show that this finding is more frequent in children

Table 13 Mean (M) and standard deviation (SD) of variables connected with tongue position for the children in groups 1 and 5

Significant differences ($P < 0.01$) between the means for the two groups are listed in the last column

Variable		Total	Group					Significant differences $P < 0.01$
			1 Controls No adenoids $n = 37$	2 Controls Small adenoids $n = 33$	3 Controls Large adenoids $n = 11$	4 Adenoid- ectomy Otit med. $n = 21$	5 Adenoid- ectomy Nasal obstr $n = 60$

	n	50	22				28	

greater in group 5 compared with groups 1 3 and 4 as well as in group 2 compared with group 1

The angle between the mandibular line and the nasal line (A107) is significantly greater in group 5 than in groups 1 3 and 4

The angle between pterygomaxillare (pm) and the midpoint of sella turcica (s) and basion (ba) (A109) is significantly smaller in group 5 than in groups 2 and 3

Body height (A128) is significantly smaller in group 3 than in groups 1 and 5

The index for face width/face height (A111) is significantly lower in group 5 than in groups 1 2 and 3

The index for depth of cranial base/face height (A114) is significantly lower in group 5 than in groups 1 2 3 and 4

The index for face depth/face height (A115) is significantly lower in group 5 than in groups 1 2 and 4 Height of upper lip (A96) and height of lower lip (A97) are both significantly larger in group 5 than in group 3

The majority of the significant intergroup differences in Table 12 refer to the children in

group 5 on the one hand and those in one or several of groups 1-4 on the other

Summary

Table 12 indicates that, in relation to one or several of the other groups, the children who underwent adenoidectomy for obstructed nose breathing (group 5) have on the average a large face height, short nasopharynx in the sagittal plane a great tendency to small values for the angles s-n-as and s-n-sm a great angle between the mandibular and the nasio-sella lines as well as the nasal line, low indexes for face width/height face depth/height and depth of cranial base/face height as well as great height of upper and lower lips The children in group 5 thus appear to have a particular facial morphology

Variables for tongue position

The results for variables that express the position of the tongue in relation to the hard and soft palates are given in Table 13

Considerably fewer children are represented in Table 13 than in the other groups of varia-

Table 14 Correlations between all pairs of variables for anamnesis and clinical status

Swollen nasal mucosa	18				22														
Septum deviation	19																		

Index for width of lower and upper arches (A63) and an index for height of palatal vault and upper arch width (A66) variables for the inclination of the upper and lower incisors (A46-48) and variables for the angles between the occlusal line and the mandibular and nasion-sella lines (A44-45)

These correlations indicate that children who breath through the mouth tend to have a narrow upper arch, crossbite or a tendency to crossbite, short lower jaw retroclination of upper and lower incisors, and large angles between the occlusal line and the mandibular and nasion-sella lines.

There is also a significant correlation between prolonged finger suckers (A10) and small overbite (A56)

Large tonsils (A17) is significantly correlated with the dentition variables that express the vertical relationship between the upper and lower arches (A44 and A56) The presence of large tonsils appears to be associated with a small overbite.

Year of birth (A02) shows significant correlations with several dentition variables, i.e. width of upper arch between the first deciduous molars (A52), overbite (A56) height of palatal vault (A60) space difference of upper arch (A61) and the index for height of palatal vault and upper arch width (A66) Correlations between age and dentition variables are to be expected in particular when the latter represent measurements of size

Summary

The significant correlations shown in Table 15 between variables for anamnesis and clinical status on the one hand and dentition variables on the other confirm the suspicion that there is a relationship between mode of breathing and characteristics of the dentition. They indicate that children who breath through the mouth have a narrow upper arch, crossbite or a tendency to crossbite, short lower arch, retroclination of upper and lower incisors, and

who suffer from recurrent infections in the ear nose and throat as well as in mouth breathers

Table 14 also indicates that children who sleep with the mouth open (A05) frequently have siblings who suffer from ear nose and throat diseases (A09)

Summary

The correlations shown in Table 14 are dominated by the positive relationships between mouth breathing on the one hand and variables for the nasal airway on the other. The correlation between mouth breathing and enlarged adenoids is particularly marked. The presence of large tonsils, on the other hand appears to be of less importance for mode of breathing.

Variables for anamnesis and clinical status correlated with dentition variables

Correlations between variables for anamnesis and clinical status on the one hand and dentition variables on the other are shown in Table 15. Variable A51 Arch width 04-04 upper is not included as it correlates strongly with A49 Arch width M₁-M₁ upper.

There are a great many significant correlations ($P < 0.01$). The majority of substantial correlations refer to breathing variables (A04-05 A13-16) on the one hand and on the other variables that express width of upper arch at first molars (A49 and A66) and length of lower arch (A54) variables representing an

index for width of lower and upper arches (A63) and an index for height of palatal vault and upper arch width (A66) variables for the inclination of the upper and lower incisors (A46-48) and variables for the angles between the occlusal line and the mandibular and nasion-sella lines (A44-45).

These correlations indicate that children who breath through the mouth tend to have a narrow upper arch, crossbite or a tendency to crossbite, short lower jaw retroclination of upper and lower incisors, and large angles between the occlusal line and the mandibular and nasion-sella lines.

There is also a significant correlation between prolonged finger suckers (A10) and small overbite (A56).

Large tonsils (A17) is significantly correlated with the dentition variables that express the vertical relationship between the upper and lower arches (A44 and A56). The presence of large tonsils appears to be associated with a small overbite.

Year of birth (A02) shows significant correlations with several dentition variables, i.e. width of upper arch between the first deciduous molars (A52), overbite (A56), height of palatal vault (A60), space difference of upper arch (A61), and the index for height of palatal vault and upper arch width (A66). Correlations between age and dentition variables are to be expected in particular when the latter represent measurements of size.

Summary

The significant correlations shown in Table 15 between variables for anamnesis and clinical status on the one hand and dentition variables on the other confirm the suspicion that there is a relationship between mode of breathing and characteristics of the dentition. They indicate that children who breath through the mouth have a narrow upper arch, crossbite or a tendency to crossbite, short lower arch, retroclination of upper and lower incisors, and

who suffer from recurrent infections in the ear nose and throat as well as in mouth breathers

Table 14 also indicates that children who sleep with the mouth open (A05) frequently have siblings who suffer from ear nose and throat diseases (A09)

Summary

The correlations shown in Table 14 are dominated by the positive relationships between mouth breathing on the one hand and variables for the nasal airway on the other. The correlation between mouth breathing and enlarged adenoids is particularly marked. The presence of large tonsils, on the other hand appears to be of less importance for mode of breathing.

Variables for anamnesis and clinical status correlated with dentition variables

Correlations between variables for anamnesis and clinical status on the one hand and dentition variables on the other are shown in Table 15. Variable A51 Arch width 04-04 upper is not included as it correlates strongly with A49 Arch width M₁-M₁ upper.

There are a great many significant correlations ($P < 0.01$). The majority of substantial correlations refer to breathing variables (A04-05 A13-16) on the one hand and on the other variables that express width of upper arch at first molars (A49 and A66) and length of lower arch (A54) variables representing an

as half the number of children had undergone adenoidectomy in the interval and this presumably improved their nasal airflow.

There are significant negative correlations between the number of ailments with ear, nose and throat diseases (A09) and airflow variables A67 and A70. This is probably explained by the positive relationship between variable A09 and size of adenoids (A20) reported in Table 16.

The age variable (A02) also displays significant correlations with airflow variables A70 and A76. Since age is expressed by year of birth, low ages are represented by high values and consequently a positive relationship between airflow and increasing age is denoted with a minus sign.

Summary

The significant negative correlations in Table 17 between anamnesis and clinical status variables expressing nasal obstruction on the one hand and nasal airflow on the other indicate

that there is good agreement between the subjective and objective methods of registration employed in this investigation.

Variables for anamnesis and clinical status correlated with skeleton and lip variables

Significant correlations between anamnesis and clinical status variables on the one hand and skeleton and lip variables on the other are presented in Table III. Variables A12, A81, A98, A112 and A126 are not included as they correlate very strongly with variables A15, A88, A99, A113 and A87 respectively.

Many of the correlations between these variables are significant ($P < 0.01$).

The age variable (A02) is significantly correlated to the majority of skeleton and lip variables, the strongest relationship ($r = 0.86$) being with body height (A128). It is particularly interesting that there is no significant correlation between age and the sagittal depth

large angles between the occlusal line on the one hand and the mandibular and nasion-sella lines on the other. In addition the presence of large tonsils appears to be associated with a small overbite.

Variables for anamnesis and clinical status correlated with adenoid variables

Significant correlations between variables for anamnesis and clinical status on the one hand and adenoid variables on the other are shown in Table 16. Variables A34–36 and A38–41 are not included since they correlate strongly with A33, A26, A27, A29, A30, A26 and A27 respectively.

There are several relatively strong correlations between the variables for mode of breathing (A04–05, A15) and those for preoperative size of adenoids in relation to the nasopharynx (A20, A26, A29 and A32). This strongly suggests that mouth breathing is a consequence of enlarged adenoids.

It was to be expected that the anamnesis and clinical status variables which express mode of breathing (A04–05, A15) or the causes and presence of nasal obstruction (A06, A13–14, A16 and A18) would be significantly correlated with the variables for indications for adenoidectomy, i.e. obstructed nose breathing (A22), recurrent infection (A23) and otitis media (A24). It is particularly interesting to note the strong positive correlations obtained between preoperative size of adenoids (A20) and the indication recurrent otitis media (A24) on the one hand and on the other number of siblings with ear, nose and throat diseases (A09).

From Table 16 it will also be seen that year of birth (A02) shows significant positive correlations with relative size of adenoids (A20 and A32) as well as with recurrent infection as an indication for adenoidectomy (A23). This indicates that size of adenoids in relation to the nasopharynx decreases with increasing age.

Good agreement between clinical and radio-

graphic assessments of the size of adenoids in relation to the nasopharynx is indicated by the high significant correlations ($r = > 0.60$) between the otologist's clinical assessments (A16) and the author's estimates (A20) and measurements (A32) on lateral cephalometric radiographs.

Summary

Table 16 shows that there are marked relationships between mode of breathing and size of adenoids. There are strong indications that mouth breathing is a consequence of enlarged adenoids on the posterior wall of the nasopharynx. The correlations in the table also indicate that size of adenoids decreases with increasing age and that there is good agreement between clinical and radiographic assessments of size of adenoids.

Variables for anamnesis and clinical status correlated with airflow variables

Table 17 shows significant correlations between anamnesis and clinical status on the one hand and variables for nasal airflow measured at a differential pressure of 10 mm H₂O before and after nose drops on two occasions on the other. The airflow measurements at differential pressures of 15 and 20 mm H₂O are not included in view of the strong intercorrelations displayed by these and the measurements at 10 mm H₂O ($r > 0.97$). Variable A12, Open or closed mouth, is not included either as it correlates strongly ($r = 0.87$) with variable A15.

There is a large number of correlations which are significant at the 1% level ($r > 0.20$). Most of them concern relationships between anamnesis and clinical status variables for obstructed nose breathing (A05, A13–16, A18) on the one hand and nasal airflow before (A67) as well as after (A70) nose drops at the first examination on the other. These relationships could not be demonstrated at the second examination, which was only to be expected

of the bony nasopharynx (A92). Nor is age significantly correlated with the variables representing the angles s-n-ss and ss-n-sm (A102 and A103 respectively).

There are also several significant correlations between sex (A03) and the skeleton and lip variables. Thus, boys have higher values than girls for variables concerning length of cranial base (A85 A87) sagittal depth of bony nasopharynx (A92) length of upper and lower lip (A96 and A97 respectively) and angle between lower and upper jaw (A107). The girls, on the other hand, have a significantly higher index for face width/face height (A111).

A large number of significant correlations concern variables connected with obstructed nose breathing (A04-05 A13-16) on the one hand and on the other variables concerning face height (A88 A106 A111 A114 A115) sagittal depth of face (A124) sagittal depth of nasopharynx (A92, A109 A125) angle between upper and lower jaws (A107) index for

face width/face height (A111 A113) and face depth/face height (A114-115). Thus children who are mouth breathers (A04 A15) and/or have nasal obstructions (A13-14 A16) have a high face height with a large angle between the upper and lower jaws a short nasopharynx in the sagittal plane, a small index for face width/face height and a small face depth. Mouth breathers also appear to have long upper and lower lips.

Table 18 also shows that prolonged finger suckers (A10) are correlated with the variables for face height (A88) length of lower lip (A97) sagittal depth of bony nasopharynx (A109) and the indexes for face depth/face height (A114-115 A117). The sign of these correlations is the opposite of that for the corresponding correlations with the variables for mode of breathing mentioned above. This is in keeping with the fact that groups 1 2 and 3 have the highest proportion of finger suckers (cf Table 7 p 38).

(120) The variables that express the inclination of the upper and lower incisors in relation to the nasion-sella line (A46) and the mandibular line (A48) as well as their mutual inclination (A47) display high correlations with the variables for arch width (A49–A52, A63 and A64) and arch length (A53–54 and A65). This indicates that retroclination of the incisors is more frequent in upper and/or lower arches that are narrow and short.

Width of upper arch between the first molars (A49) is significantly correlated to other variables for arch width (A50–A52, A59 and A63–64) as well as to variables that express the length of the upper and lower arches (A53 and A54 respectively) and those for the space difference of the upper and lower arches (A61 and A62 respectively).

The variables for upper arch width also display significant positive and negative correlations respectively with those for overbite (A56) and the angle between the occlusal and nasion-sella lines (A45). The correlations with height of palatal vault (A60–A66) on the other hand are not significant. This indicates that a narrow upper arch is frequently associated with

upper and lower arches that are short and crowded. The incidence of crossbite also appears to be high among children with a narrow upper jaw as do the incidences of overbite and a large angle between the occlusal and nasion-sella lines.

The only significant correlation for height of palatal vault (A60) in Table 20 concerns a positive relationship with overbite (A56).

A small overbite (A56) also appears to be common in cases with crossbite (A59) judging from the significant negative correlation between these variables. There is also a significant negative correlation between overbite (A56) and the angle between the occlusal and mandibular lines (A44). The latter variable in its turn displays a significant negative correlation with the angle between the lower incisors and the mandibular line (A48).

Overjet (A55) shows significant negative correlations with the variables that express the sagittal distance between the mesial surfaces of the first upper and lower molars on the right and left (A57 and A58 respectively). In keeping with the definitions of the latter variables, positive values were noted when the

do not display any significant correlations with freeway space between the upper and lower jaws with the lower jaw in the rest position (A43)

Summary

The significant correlations shown in Table 20 indicate that:

narrow short arch in the upper as well as the lower jaw frequently involves retroclination of the incisors in relation to the nasion-sella line and the mandibular line;

narrow upper arch occurs frequently in short, crowded lower and upper jaws and is frequently associated with small overbite and a large angle between the occlusal and nasion-sella lines;

small overbite is common in children with crossbite.

large overjet occurs frequently among children with a postnormal relation between the upper and lower first molars and a long upper arch; short lower arch is frequently associated with retroclined upper and lower incisors, large sagittal distance between the mesial surfaces of the lower and upper first molars, crowded lower jaw and a short upper arch.

Dentition variables correlated with adenoid variables

Correlations between dentition variables and adenoid variables are shown in Table 21. Variables A34-36, A51, A38-39 and A40-41 are not included as they correlate strongly with A33, A26-27, A49, A29-30 and A26-27 respectively.

mesial surface of the lower molar was more mesial than the corresponding surface of the upper molar. These findings indicate that large overjet is significantly correlated to a postnormal relation between the first upper and lower molars. This relationship also agrees with the significant positive correlation between overjet (A55) and the sagittal distance between subspinale and supramentale projected onto the occlusal line (A42).

Overjet (A55) also shows a significant correlation with length of upper arch (A53) but not with length of lower arch (A54).

In addition to the significant correlations already mentioned with variables for the inclina-

tion of the upper and lower incisors (A46, A47 and A48) and for width of upper arch (A49) length of lower arch (A54) is also significantly correlated with length of upper arch (A53) sagittal relation between the mesial surfaces of the upper and lower first molars (A57-58) and space difference of lower arch (A62).

Thus, a short lower arch appears to be frequently associated with retroclination of the upper and lower incisors, a large sagittal distance between the mesial surfaces of the upper and lower first molars, a crowded lower jaw and short length of upper arch.

The dentition variables listed in Table 20

[illegible]

A32) and those for arch width between first molars (A49) and the index for widths of lower and upper jaws between first molars (A63). Children with enlarged adenoids on the posterior wall of the nasopharynx thus appear prone to have a narrow upper arch and crossbite.

Synonyms

The significant correlations in Table 21 between dentition and adenoid variables support the assumption of a relationship between the occurrence of adenoids and special characteristics of the dentition. The relationship indicates that children with adenoids frequently have a narrow upper jaw crossbite or a tendency to

crossbite, retroclined upper and lower incisors, a short lower jaw and large angles between the occlusal line and the mandibular and nasion-sella lines.

Dentition variables correlated with air-flow variables

Significant correlations between dentition variables and variables for nasal airflow measured in l/min at a differential pressure of 10 mm H₂O before and after nose drops on two occasions are shown in Table 22. Variable A51 is not included as it correlates strongly with variable A49.

Table 23. Correlations between dentition variables and variables for the skeleton and lips

There is a considerable number of significant correlations ($P < 0.01$). The majority concern the dentition variables that express the inclination of upper and lower incisors (A46-48) and the angle between the occlusal and nasion-sella lines (A45) on the one hand and, on the other variables for size of adenoids in relation to the nasopharynx (A20-A32) and obstructed nose breathing as an indication for adenoidectomy (A22).

Thus, children whose adenoids are large in relation to the nasopharynx and who also suffer from nasal obstruction frequently display retroclination of the upper and lower incisors as well as a large angle between the occlusal

and nasion-sella lines. Obstructed nose breathing as an indication for adenoidectomy (A22) is also significantly correlated with length of lower jaw (A54), crossbite (A59-A63) and the angle between the occlusal and mandibular lines (A44).

Besides having retroclined upper and lower incisors, children who undergo adenoidectomy on account of obstructed nose breathing frequently display a short lower jaw, a large angle between the occlusal and mandibular lines and crossbite.

It is also interesting to note the significant correlations between variables for size of adenoids in relation to the nasopharynx (A20

The inclination of the upper incisors in relation to the nasion-sella line (A46) shows significant positive correlations with the angles $s-n-as$ and $s-n-sm$ (A102, A104 and A103 respectively) as well as the angle $ss-n-ba$ (A124).

A greater number of significant correlations are found for the inclination of the lower incisors in relation to the mandibular line (A48) and the skeleton and lip variables, i.e. variables of depth of face (A87 A91), face height (A88), angle of mandibular line in relation to nasion-sella line (A106) and nasal line (A107), sagittal depth of bony nasopharynx (A92, A109), distance between pterygomaxillare and zomion (A121), and the angles $s-n-as$ (A102), $ss-n-ba$ (A124) and $ss-n-sm$ (A105). Thus, children with retroclined lower incisors frequently have small face depth, large face height, large angles between the mandibular and the nasion-sella (A106) and nasal lines (A107), small sagittal depth of nasopharynx, low height of posterior choanal aperture and small values for the angles $s-n-as$ and $ss-n-sm$.

The variables for arch width (A49 A50 A52) also display a large number of significant correlations with the skeleton and lip variables. However as these dentition variables display relatively strong intercorrelations ($r > 0.58$) the present account will be confined to the one with the greatest number of significant correlations with the skeleton variables, namely A49. Upper arch width between first molars.

Variable A49 is significantly correlated to the variables for face width (A80), nose width over alae nasi (A82), width (A100) and height (A121) of posterior choanal aperture, face depth (A87 A91), depth of anterior cranial base (A85), angle of mandibular line in relation to the nasion-sella line (A106) and to the nasal line (A107), posterior upper face height (A94), volume and sagittal depth of bony nasopharynx (A101 and A92 respectively), the angles $s-n-as$ (A102, A104), and $s-n-sm$ (A103), and body height (A128). Thus, children with a narrow upper arch between the first molars more frequently have a narrow face and nose, a short face and cranial base depth, low

posterior upper face height, a low and narrow posterior choanal aperture, a small volume and sagittal depth of the nasopharynx, large angles between the mandibular and the nasion-sella and nasal lines, small values for the angles $s-n-as$ and $s-n-sm$, and small body height.

Length of upper arch (A53) shows significant correlations with only a few skeleton variables, viz. nose width (A82), face depth (A91), posterior upper face height (A94) and height of posterior choanal aperture (A121). All these correlations are positive.

Length of lower arch (A54) is significantly correlated not only with the same skeleton variables as length of upper arch but also with variables for sagittal depth of bony nasopharynx (A92), the angle $s-n-as$ (A102, A104), the angle $ss-n-ba$ (A124), and the index for face depth/face height (A115 A117). These correlations are also positive.

Overjet (A55) is also significantly correlated with several skeletal variables, viz. face depth (A91), cranial base depth (A85 A87), posterior upper face height (A86 A94 A127), the angle $s-n-sm$ (A103), the angle $ss-n-sm$ (A105) and the sagittal cross-section of the bony nasopharynx (A123). Thus, children with large overjet frequently have a large face depth, large cranial base depth, large posterior upper face height, a tendency to small values for the angle $s-n-sm$, large values for the angle $ss-n-sm$, and a large sagittal cross-section of the bony nasopharynx.

Overbite (A56) is significantly correlated with the variables for face width (A80), face depth (A91), cranial base depth (A85 A87), anterior and posterior upper face height (A89 A116 and A86, A94 A127 respectively), height of posterior choanal aperture (A121), volume of bony nasopharynx (A101), angle of mandibular line in relation to nasion-sella line (A106) and to nasal line (A107), and body height (A128). Thus, children with a small overbite more frequently have a small face width, small face and cranial base depth, small anterior and posterior upper face height, low posterior choanal aperture, small volume of

The significant correlations chiefly refer to the relationship between variables for inclination of upper and lower incisors (A46 and A48 respectively) and the angle between the occlusal and nasion-sella lines (A45) on the one hand and airflow variables before adenoidectomy before (A67) as well as after (A70) nose drops on the other. Variables A46 and A45 also show significant correlations with A76. Airflow after nose drops after adenoidectomy. The correlations indicate that retroclination of upper and lower incisors and a large angle between the occlusal and nasion-sella lines are more common among children with a low nasal airflow.

Width of upper arch between first molars (A49) is also significantly correlated to airflow after nose drops before adenoidectomy (A70) as well as to airflow before and after nose drops one month after adenoidectomy (A73 and A76 respectively). A narrow upper arch is thus common among children with a low nasal airflow.

Length of lower arch (A54) also displays a significant positive correlation to nasal airflow before nose drops before adenoidectomy (A67). Crossbite or a tendency to crossbite (A63) displays a significant negative correlation with nasal airflow after nose drops after adenoidectomy (A76).

Summary

The correlations in Table 22 show that low nasal airflow is common among children with a narrow upper arch, retroclination of upper and lower incisors, a large angle between the occlusal and nasion-sella lines, a short lower arch and crossbite.

Dentition variables correlated with skeleton and lip variables

Significant correlations between dentition variables and variables for the skeleton and lips are shown in Table 23. Variables A51-A81

A98-A112 and A126 are not included as they correlate strongly with variables A49-A88-A99-A113 and A87 respectively.

There is a very large number of significant correlations ($P < 0.01$).

An interesting finding is the significant positive correlation for the distance between subspinale and supramentale projected onto the occlusal line (A42) in relation to the sagittal depth of the bony nasopharynx (A92).

Variable A42 also shows a significant correlation with the angle $ss-n-sm$ (A105) but the coefficient ($r = 0.36$) is not sufficiently high for these variables to be regarded as interchangeable.

The angle between the occlusal and mandibular lines (A44) shows significant positive correlations with face height (A88-A90), the angle of the mandibular line in relation to the nasion-sella line (A106) and the nasal line (A107).

More noteworthy correlations are the significant positive coefficients between A44 and the variables for height of upper lip (A96) and lower lip (A97).

The angle between the occlusal and nasion-sella lines (A45) is significantly correlated to the following variables: anterior (A89) and posterior upper face height (A86-A94-A127), angle of the mandibular line in relation to the nasion-sella line (A106) and to the nasal line (A107), sagittal depth (A92) and volume (A101) of the bony nasopharynx, distance between pterygomaxillare and hornion (A121), the angles $s-n-s$ and $s-n-sm$ (A102, A104 and A103 respectively) and the angle $ss-n-sm$ (A105).

These correlations indicate that children with a large angle between the occlusal and nasion-sella lines frequently have a high anterior but low posterior face height, a large angle for the mandibular line in relation to the nasion-sella and nasal lines, small sagittal depth and volume of nasopharynx, low posterior choanal aperture, a tendency to small values for the angles $s-n-s$ and $s-n-sm$ and a high value for the angle $ss-n-sm$.

The inclination of the upper incisors in relation to the nasion-sella line (A46) shows significant positive correlations with the angles $s-n-as$ and $s-n-sm$ (A102, A104 and A103 respectively) as well as the angle $ss-n-ba$ (A124).

A greater number of significant correlations are found for the inclination of the lower incisors in relation to the mandibular line (A48) and the skeleton and lip variables, i.e. variables for depth of face (A87 A91), face height (A88) angle of mandibular line in relation to nasion-sella line (A106) and nasal line (A107), sagittal depth of bony nasopharynx (A92, A109) distance between pterygomandibular and hornion (A121), and the angles $s-n-as$ (A102), $ss-n-ba$ (A124) and $ss-n-sm$ (A105). Thus, children with retroclined lower incisors frequently have small face depth, large face height, large angles between the mandibular and the nasion-sella (A106) and nasal lines (A107) small sagittal depth of nasopharynx, low height of posterior choanal aperture and small values for the angles $s-n-as$ and $ss-n-sm$.

The variables for arch width (A49 A50 A52) also display a large number of significant correlations with the skeleton and lip variables. However as these dentition variables display relatively strong intercorrelations ($r > 0.58$) the present account will be confined to the one with the greatest number of significant correlations with the skeleton variables, namely A49 Upper arch width between first molars.

Variable A49 is significantly correlated to the variables for face width (A80), nose width over alae nasi (A82), width (A100) and height (A121) of posterior choanal aperture, face depth (A87 A91), depth of anterior cranial base (A85), angle of mandibular line in relation to the nasion-sella line (A106) and to the nasal line (A107), posterior upper face height (A94), volume and sagittal depth of bony nasopharynx (A101 and A92 respectively), the angles $s-n-as$ (A102, A104), and $s-n-sm$ (A103), and body height (A128). Thus, children with a narrow upper arch between the first molars more frequently have a narrow face and nose a short face and cranial base depth, low

posterior upper face height, a low and narrow posterior choanal aperture, a small volume and sagittal depth of the nasopharynx, large angles between the mandibular and the nasion-sella and nasal lines, small values for the angles $s-n-as$ and $s-n-sm$, and small body height.

Length of upper arch (A53) shows significant correlations with only a few skeleton variables viz. nose width (A82), face depth (A91), posterior upper face height (A94) and height of posterior choanal aperture (A121). All these correlations are positive.

Length of lower arch (A54) is significantly correlated not only with the same skeleton variables as length of upper arch but also with variables for sagittal depth of bony nasopharynx (A92), the angle $s-n-as$ (A102, A104), the angle $ss-n-ba$ (A124), and the index for face depth/face height (A115 A117). These correlations are also positive.

Overjet (A55) is also significantly correlated with several skeletal variables, viz. face depth (A91), cranial base depth (A85 A87), posterior upper face height (A86, A94 A127), the angle $s-n-sm$ (A103) the angle $ss-n-sm$ (A105) and the sagittal cross-section of the bony nasopharynx (A123). Thus, children with large overjet frequently have a large face depth large cranial base depth, large posterior upper face height, a tendency to small values for the angle $s-n-sm$, large values for the angle $ss-n-sm$, and a large sagittal cross-section of the bony nasopharynx.

Overbite (A56) is significantly correlated with the variables for face width (A80) face depth (A91), cranial base depth (A85 A87) anterior and posterior upper face height (A89 A116 and A86, A94 A127 respectively) height of posterior choanal aperture (A121) volume of bony nasopharynx (A101), angle of mandibular line in relation to nasion-sella line (A106) and to nasal line (A107), and body height (A128). Thus, children with a small overbite more frequently have a small face width, small face and cranial base depth, small anterior and posterior upper face height, low posterior choanal aperture, small volume of

bony nasopharynx, large angles between the mandibular and the nasion-sella and nasal lines, and small body height.

The variables for the sagittal relation between the upper and lower first molars on the right and left sides (A57 and A58 respectively) display significant negative correlations with the variable for the angle $ss-n-sm$ (A105). In keeping with the definitions of variables A57 and A58 a positive sign indicates that the mesial surface of the lower molar is more mesial than the corresponding surface of the upper molar. Thus, a small value for the angle $ss-n-sm$ tends to be accompanied by a large sagittal distance between the mesial surfaces of the lower and upper molars.

The dentition variable that has the greatest number of significant correlations with the skeletal variables in Table 23 is A60 Height of palatal vault. This is significantly correlated to breadth of face and nose (A80 A99 and A82 respectively) face depth (A87 A91) total face height (A88) anterior and posterior upper face height (A89 and A86 A94 A127 respectively) anterior lower face height (A90) width and height of posterior choanal aperture (A100 and A121 respectively) volume and sagittal cross-section of bony nasopharynx (A101 and A123 respectively) height of upper and lower lip (A84 A96 and A97 respectively) body height (A128) and the indexes for face width/face height (A111 A113) and face depth/face height (A115 A117). This indicates that a high palatal vault is common in children with a wide face and nose large face depth large anterior and posterior face height, wide and high posterior choanal aperture high and large bony nasopharynx, long upper and lower lips, large body height and small indexes for face breadth/face height and face depth/face height.

The index for height of palatal vault and upper arch width between first molars (A66) also displays a large number of significant correlations with the skeletal variables in Table 23. Almost all the significant correlations are the same as those obtained for height of palatal

vault alone (A60) suggesting that this variable dominates the index variable.

The variables A61 and A62, which express the space difference in the upper and lower jaw respectively display only a few significant correlations with the skeletal variables, the only one of interest here being the positive correlation with the angle $s-n-ss > 82$ (A104).

Variable A63 which is an index between lower and upper arch widths between the first molars and can also be said to express the presence or absence of crossbite, is significantly correlated with sagittal depth of bony nasopharynx (A92) height of upper lip (A96) the angle $s-n-ss$ (A102) the index for anterior upper face height and total face height (A116) height of posterior choanal aperture (A121), and the angle $ss-n-ba$ (A124). Thus, children with crossbite as a result of the lower arch being wider than the upper at the first molars, frequently have a small sagittal depth of the bony nasopharynx, low posterior choanal aperture long upper lip a tendency to small values for the angle $s-n-ss$ and a small anterior upper face height in relation to total face height.

Summary

The majority of dentition values display significant correlations with the variables for the facial skeleton and lips in Table 23. These correlations show that:

retroclined upper incisors are common in children with small values for the angles $s-n-ss$ and $s-n-sm$

retroclined lower incisors are common in children with small face depth, large face height, large angles between the mandibular line and the nasion-sella and nasal lines, small sagittal depth of nasopharynx, low posterior choanal aperture, and a tendency to small values for the angles $s-n-ss$ and $ss-n-sm$

a narrow upper arch between the first molars is common among children with a narrow face and nose short face depth and cranial base depth small posterior upper face height, a low and narrow posterior choanal aperture small

nasopharynx, large angles between the mandibular line and the nasal and nasion-sella lines, small values for the angles s-n-as and s-n-sm, and small body height,

large overjet is common among children with large face depth and cranial base depth, large posterior upper face height, a tendency to small values for the angle s-n-sm and large values for ss-n-sm, and large sagittal depth of nasopharynx

small overbite is common among children with small face width, small face depth and cranial base depth, small anterior as well as posterior upper face height, low posterior choanal aperture small nasopharynx, large angles between the mandibular line and the nasal and nasion-sella lines, and small body height

crossbite is common in children with small sagittal depth of nasopharynx, low posterior

choanal aperture, long upper lip, a tendency to small values for the angle s-n-as and a small anterior upper face height in relation to total face height.

Dentition variables correlated with variables for tongue position

Significant correlations between dentition variables and variables for tongue position are given in Table 24. Variable A51 is not included as it correlates strongly with variable A49.

Only a few correlations are significant ($P < 0.01$). The majority are positive correlations between tongue position in relation to pterygo-maxillare and basion (A129 and A130 respectively) on the one hand and variables for height

bony nasopharynx, large angles between the mandibular and the nasion-sella and nasal lines, and small body height

The variables for the sagittal relation between the upper and lower first molars on the right and left sides (A57 and A58 respectively) display significant negative correlations with the variable for the angle $ss-n-sm$ (A105). In keeping with the definitions of variables A57 and A58 a positive sign indicates that the mesial surface of the lower molar is more mesial than the corresponding surface of the upper molar. Thus a small value for the angle $ss-n-sm$ tends to be accompanied by a large sagittal distance between the mesial surfaces of the lower and upper molars.

The dentition variable that has the greatest number of significant correlations with the skeletal variables in Table 23 is A60 Height of palatal vault. This is significantly correlated to breadth of face and nose (A80, A99 and A82 respectively), face depth (A87, A91), total face height (A88), anterior and posterior upper face height (A89 and A86, A94, A127 respectively), anterior lower face height (A90), width and height of posterior choanal aperture (A100 and A121 respectively), volume and sagittal cross-section of bony nasopharynx (A101 and A123 respectively), height of upper and lower lip (A84, A96 and A97 respectively), body height (A128) and the indexes for face width/face height (A111, A113) and face depth/face height (A115, A117). This indicates that a high palatal vault is common in children with a wide face and nose, large face depth, large anterior and posterior face height, wide and high posterior choanal aperture, high and large bony nasopharynx, long upper and lower lips, large body height and small indexes for face breadth/face height and face depth/face height.

The index for height of palatal vault and upper arch width between first molars (A66) also displays a large number of significant correlations with the skeletal variables in Table 23. Almost all the significant correlations are the same as those obtained for height of palatal

vault alone (A60) suggesting that this variable dominates the index variable.

The variables A61 and A62, which express the space difference in the upper and lower jaw respectively, display only a few significant correlations with the skeletal variables, the only one of interest here being the positive correlation with the angle $s-n-as$ $> 82^\circ$ (A104).

Variable A63, which is an index between lower and upper arch widths between the first molars and can also be said to express the presence or absence of crossbite, is significantly correlated with sagittal depth of bony nasopharynx (A92), height of upper lip (A96), the angle $s-n-as$ (A102), the index for anterior upper face height and total face height (A116), height of posterior choanal aperture (A121) and the angle $ss-n-ba$ (A124). Thus, children with crossbite as a result of the lower arch being wider than the upper at the first molars, frequently have a small sagittal depth of the bony nasopharynx, low posterior choanal aperture, long upper lip, a tendency to small values for the angle $s-n-as$ and a small anterior upper face height in relation to total face height.

Summary

The majority of dentition values display significant correlations with the variables for the facial skeleton and lips in Table 23. These correlations show that:

retroclined upper incisors are common in children with small values for the angles $s-n-as$ and $s-n-sm$.

retroclined lower incisors are common in children with small face depth, large face height, large angles between the mandibular line and the nasion-sella and nasal lines, small sagittal depth of nasopharynx, low posterior choanal aperture and a tendency to small values for the angles $s-n-as$ and $ss-n-sm$.

a narrow upper arch between the first molars is common among children with a narrow face and nose, short face depth and cranial base depth, small posterior upper face height, a low and narrow posterior choanal aperture, small

nasopharynx, large angles between the mandibular line and the nasal and nasion-sella lines, small values for the angles s-n-as and s-n-sm, and small body height.

Large overjet is common among children with large face depth and cranial base depth, large posterior upper face height, a tendency to small values for the angle s-n-sm and large values for ss-n-sm, and large sagittal depth of nasopharynx.

Small overbite is common among children with small face width, small face depth and cranial base depth, small anterior as well as posterior upper face height, low posterior choanal aperture, small nasopharynx, large angles between the mandibular line and the nasal and nasion-sella lines, and small body height.

Crossbite is common in children with small sagittal depth of nasopharynx, low posterior

choanal aperture, long upper lip and a tendency to small values for the angle s-n-as and a small anterior upper face height in relation to total face height.

Dentition variables correlated with variables for tongue position

Significant correlations between dentition variables and variables for tongue position are given in Table 24. Variable A51 is not included as it correlates strongly with variable A49.

Only a few correlations are significant ($P < 0.01$). The majority are positive correlations between tongue position in relation to pterygo-maxillare and basion (A129 and A130 respectively) on the one hand and variables for height

bony nasopharynx large angles between the mandibular and the nasion-sella and nasal lines, and small body height

The variables for the sagittal relation between the upper and lower first molars on the right and left sides (A57 and A58 respectively) display significant negative correlations with the variable for the angle $ss-n-sm$ (A105). In keeping with the definitions of variables A57 and A58 a positive sign indicates that the mesial surface of the lower molar is more mesial than the corresponding surface of the upper molar. Thus a small value for the angle $ss-n-sm$ tends to be accompanied by a large sagittal distance between the mesial surfaces of the lower and upper molars.

The dentition variable that has the greatest number of significant correlations with the skeletal variables in Table 23 is A60 Height of palatal vault. This is significantly correlated to breadth of face and nose (A80 A99 and A82 respectively) face depth (A87 A91) total face height (A88) anterior and posterior upper face height (A89 and A86 A94 A127 respectively) anterior lower face height (A90) width and height of posterior choanal aperture (A100 and A121 respectively) volume and sagittal cross section of bony nasopharynx (A101 and A123 respectively) height of upper and lower lip (A84 A96 and A97 respectively) body height (A128) and the indexes for face width/face height (A111 A113) and face depth/face height (A115 A117). This indicates that a high palatal vault is common in children with a wide face and nose, large face depth, large anterior and posterior face height, wide and high posterior choanal aperture, high and large bony nasopharynx, long upper and lower lips, large body height and small indexes for face breadth/face height and face depth/face height.

The index for height of palatal vault and upper arch width between first molars (A66) also displays a large number of significant correlations with the skeletal variables in Table 23. Almost all the significant correlations are the same as those obtained for height of palatal

vault alone (A60) suggesting that this variable dominates the index variable.

The variables A61 and A62 which express the space difference in the upper and lower jaw respectively display only a few significant correlations with the skeletal variables, the only one of interest here being the positive correlation with the angle $s-n-ss > 82^\circ$ (A104).

Variable A63 which is an index between lower and upper arch widths between the first molars and can also be said to express the presence or absence of crossbite is significantly correlated with sagittal depth of bony nasopharynx (A92) height of upper lip (A96), the angle $s-n-ss$ (A102) the index for anterior upper face height and total face height (A116), height of posterior choanal aperture (A121), and the angle $ss-n-ba$ (A124). Thus, children with crossbite as a result of the lower arch being wider than the upper at the first molars, frequently have a small sagittal depth of the bony nasopharynx, low posterior choanal aperture, long upper lip, a tendency to small values for the angle $s-n-ss$ and a small anterior upper face height in relation to total face height.

Summary

The majority of dentition values display significant correlations with the variables for the facial skeleton and lips in Table 23. These correlations show that

retroclined upper incisors are common in children with small values for the angles $s-n-ss$ and $s-n-sm$

retroclined lower incisors are common in children with small face depth, large face height, large angles between the mandibular line and the nasion-sella and nasal lines, small sagittal depth of nasopharynx, low posterior choanal aperture and a tendency to small values for the angles $s-n-ss$ and $ss-n-sm$

a narrow upper arch between the first molars is common among children with a narrow face and nose, short face depth and cranial base depth, small posterior upper face height, a low and narrow posterior choanal aperture, small

The high significant correlations between variables for size of adenoids (A26-A29-A37) are a consequence of the definitions of these variables.

Summary

Table 25 shows that the radiographic assessment of adenoid size is strongly correlated with adenoid size measured planimetrically on lateral cephalometric radiographs. It also shows that the children who underwent adenoidectomy for obstructed nose breathing have a larger size of adenoids than those who underwent the operation on account of recurrent otitis media.

Adenoid variables correlated with airflow variables

Table 26 shows significant correlations between adenoid variables and variables for nasal airflow measured in l/min at a differential pressure of 10 mm H₂O before and after nose drops before and after adenoidectomy. Variables A34-36 and A38-41 are not included as

they correlate strongly with variables A32, A27, A29-30, A26 and A27 respectively.

Correlations that are significant at the 1% level chiefly refer to variables for size of adenoids (A20-A32) on the one hand and those for airflow before adenoidectomy (A67-A70) on the other. Thus, children with enlarged adenoids frequently had a small nasal airflow.

Obstructed nose breathing as an indication for adenoidectomy (A22) is significantly correlated at the 0.1% level with preoperative nasal airflow before and after nose drops (A67 and A70 respectively).

The clinical assessment of nose breathing in children who were adenoidectomized for nasal obstruction is thus in good agreement with the results of objective recordings of nasal airflow.

Summary

The significant correlations in Table 26 between nasal airflow and size of adenoids support the assumption that enlarged adenoids in the nasopharynx impairs the ability to breathe through the nose.

of palatal vault (A60 A66) on the other. Thus, not unexpectedly the distance between the tongue and the hard palate is usually large in children with a high palatal vault.

There is also a significant correlation between space difference of lower arch (A62) and tongue position in relation to the soft palate (A131) indicating that children with a widely spaced lower dentition frequently have a large distance between the tongue and the soft palate.

The other significant correlation refers to a positive relationship for the angle between the mandibular and occlusal lines (A44) and the variable for tongue position in relation to pterygomaxillare (A129).

Summary

The significant correlations shown in Table 24 confirm the assumption of a relationship between certain characteristics of the dentition and tongue position. The relationship indicates that the distance between tongue and hard palate is frequently large in children with a large angle between the occlusal and mandibular lines and a high palatal vault.

Correlations between adenoid variables

Significant correlations are presented in Table 25 for most pairs of adenoid variables. Variables A34-36 and A38-41 are not included as they correlate very strongly ($r \geq 0.85$) with variables A33 A32, A27 A29 A30 A26 and A27 respectively.

There is a very large number of significant correlations ($P < 0.01$).

The radiographic estimate of adenoid size in relation to the bony nasopharynx (A20) is strongly correlated ($r = 0.74$) with the same relationship measured planimetrically on lateral radiographs (A32). Variable A20 is also strongly correlated ($r = 0.64$) to obstructed nose breathing as an indication for adenoidectomy (A22) whereas its correlation with recurrent otitis media as an indication for adenoidectomy (A24) is considerably weaker ($r = 0.27$). The difference between these two correlations is in line with the differences between the means for variable A20 in groups 4 and 5.

The high significant correlation between obstructed nose breathing (A22) and recurrent infection (A23) as indications for adenoidectomy was to be expected.

Adenoid variables correlated with skeleton and lip variables

Significant correlations between adenoid variables and variables for the facial skeleton and lips are shown in Table 27. Variables A81, A98, A112, A126, A34, A35, A36, A38, A39, A40 and A41 are not included as they correlate very strongly ($r > 0.85$) with variables A88, A99, A113, A87, A33, A32, A27, A29, A30, A26 and A27 respectively.

There is a large number of significant correlations ($P < 0.01$).

Particularly noteworthy are the significant correlations between skeleton and lip variables and the adenoid variables A20, A32 and A22. i.e. preoperative size of adenoids in relation to the bony nasopharynx as assessed and measured on radiographs and obstructed nose breathing as an indication for adenoidectomy respectively.

Variables A20 and A32 are significantly correlated with variables that express the sagittal depth and volume of the bony nasopharynx (A92, A118 and A101 respectively), posterior upper face height (A94), the angles s-n-ss and s-n-sm (A102 and A103 respectively), the angle ss-n-ba (A124) and the angles between the mandibular line and the nasion-sella and nasal lines (A106 and A107 respectively). Large adenoids in relation to the bony nasopharynx are thus frequent among children with a small nasopharynx, low posterior upper face height, a tendency to small values for the angles s-n-ss and s-n-sm and large angles between the mandibular line and the nasion-sella and nasal lines.

Obstructed nose breathing as an indication for adenoidectomy (A22) is significantly correlated with total face height (A88), lower face height (A90), height of upper and lower lips (A96 and A97 respectively), size of the angles

[illegible]

s-n-si, s-n-sn and sn-n-ba (A102, A103 and A124 respectively), the angles between the mandibular line and the nasion-sella and nasal lines (A106 and A107 respectively), sagittal depth of bony nasopharynx (A109 A125 and A118), indexes for face width/face height (A111 A113) the index for cranial base depth/face height (A114) and the indexes for face depth/face height and face depth/anterior upper face height (A115 and A117 respectively).

Summary

The significant correlations in Table 2.7 confirm the assumption that enlarged adenoids on the posterior wall of the nasopharynx and obstructed nose breathing as a consequence of this are common in children with a particular type of facial skeleton. The relationships indicate that individuals who undergo adenoidectomy for obstructed nose breathing frequently

display large face height, large height of upper and lower lips, a tendency to small values for the angles $s-n-s$ and $s-n-sm$, large angles between the mandibular line and the nasion-sella and nasal base, small sagittal depth of the bony nasopharynx, and small indexes for face width/face height, cranial base depth/face height and face depth/face height.

Adenoid variables correlated with variables for tongue position

Table 28 shows significant correlations between adenoid variables and variables for tongue position. Variables A34-36 and A38-41 are not included as they correlate strongly ($r > 0.85$) with variables A33 A32, A27 A29 A30 A26 and A27 respectively.

All the variables for preoperative size of adenoids (A20, A26, A29 and A32) are significantly correlated with the variables for the shortest distances between the tongue and the

hard and soft palates respectively as measured on lateral cephalometric radiographs (A129 and A131 respectively)

Obstructed nose breathing and recurrent otitis media as indications for adenoidectomy (A22 and A24 respectively) also display significant correlations with the variables for tongue position (A129 A131)

Summary

The significant correlations in Table 28 indicate that a low tongue position is encountered

frequently in children with enlarged adenoids and, as a consequence of this obstructed nose breathing or recurrent otitis media

Correlations between airflow variables

Table 29 presents simple correlations between pairs of variables for nasal airflow measured in lit/min at a differential pressure of 10 mm H₂O before and after nose drops on two occasions at an interval of one month. All the correlation coefficients are significant at the 0.1%

level. Adenoidectomy was performed on half of the children in the present investigation between the first and second examinations.

Table 29 shows very high significant correlations ($r > 0.62$) for nasal airflow between the first and second examinations before (A67 A73) as well as after (A70, A76) nose drops.

Summary

Table 29 shows high correlations for nasal air flow between the first and second examinations in spite of the fact that half the children underwent adenoidectomy in the interval.

Airflow variables correlated with skeleton and lip variables

Significant correlations between variables for nasal airflow—measured in lit/min at a differential pressure of 10 mm H_2O before and after nose drops on two occasions at an interval of one month—and variables for the facial skeleton and lips are presented in Table 30. Half of the children underwent adenoidectomy in the

interval between the first and second examinations. Variables A81 A98, A112 and A126 are not included as they correlate very strongly ($r > 0.85$) with variables A88 A99 A113 and A87 respectively.

The values for nasal airflow before the administration of nose drops (A67 A73) are to be regarded as measures of the functional air flow while the corresponding values after nose drops (A70, A76) serve as measures of airflow that is more determined by anatomical conditions.

There is a large number of significant correlations ($P < 0.01$). Since airflow after nose drops is determined by anatomical conditions to a greater extent than airflow before nose drops, the present account will be confined to correlations between airflow after nose drops at the first and second examinations (A70, A76) on the one hand and skeletal variables on the other.

These airflow variables (A70 and A76) are significantly correlated with variables for face

($r > 0.85$) to variables A88, A99 A113 and A87 respectively

There is a very large number of significant correlations ($P < 0.01$)

Summary

Significant correlations were found between the majority of the skeletal variables shown in Table 31. This applied in particular to variables that express measurements of angles or dimensions in the same projection plane.

Skeleton and lip variables correlated with variables for tongue position

Significant correlations between skeleton and lip variables on the one hand and variables for tongue position on the other are shown in Table 32. Variables A81 A98 A112 and A126 are not included as they correlate very strongly (> 0.85) to variables A88 A99 A113 and A87 respectively

The significant correlations shown in Table 32 chiefly refer to the relationship between, on the one hand, the shortest distance between the tongue and the hard palate along a perpendicular to the nasion-sella line through pterygo-maxillare (A129) and, on the other skeleton and lip variables that express face height (A88, A89) height of upper lip (A96) the angle between the mandibular and nasion-sella lines (A106) indexes for face width/face height

(A111 A113) and for cranial base depth/face height (A114)

Summary

The significant correlations shown in Table 32 between variables for tongue position and variables for the facial skeleton and lips are in good agreement with the relationships already described between variables for mode of breathing and variables for the facial skeleton and lips (cf. Table 18, p. 60)

Thus, it is common for a low tongue position to be found in children with the following skeletal characteristics: large face height, large height of upper lip, large angle between mandibular and nasion-sella lines and small index values for face width/face height and cranial base depth/face height. These skeletal characteristics are the same as those which were shown in Table 12 (p. 50) to be characteristic of the children in group 5 i.e. those who underwent adenoidectomy on account of obstructed nose breathing.

Correlations between variables for tongue position

Table 33 presents simple correlations between all pairs of variables for tongue position.

The table shows that the variables for tongue position in relation to the hard and soft palates (A129 and A131 respectively) are strongly intercorrelated ($r = 0.73$)

Table 32. *Correlations between variables for the skeleton and lips and variables for tongue position*The table only shows correlation coefficients that are significant at the 1% level ($r > 0.20$)

variables for nose width (A82) the distance from the midpoint of sella turcica to basion (A86) the angle s-n-as $> 82^\circ$ (A104) and body height (A128)

Thus, a small nasal airflow is recorded frequently among children with a narrow face and nose, short distance between sella turcica and basion short depth of face and cranial base small nasopharynx, small posterior upper face height, narrow posterior choanal aperture, small values for the angle s-n-as, a large angle between the mandibular and nasion-sella lines and small body height

Summary

The significant correlations shown in Table 30 confirm the hypothesis that there is a relationship between nasal airflow and facial type. A small nasal airflow is recorded frequently among children with a narrow face and nose, short distance between sella turcica and basion short depth of face and cranial base, small

nasopharynx low posterior upper face height, narrow posterior choanal aperture, small values for the angle s-n-as, a large angle between the mandibular and nasion-sella lines and small body height

Airflow variables correlated with variables for tongue position

No significant correlations were found between the variables for nasal airflow on the one hand and variables for tongue position (A129-131) on the other

Correlations between variables for the facial skeleton and lips

Table 31 presents simple correlations between pairs of variables for the facial skeleton and lips. Variables A81, A98, A112 and A126 are not included as they correlate very strongly

($r > 0.85$) to variables A88 A99 A113 and A87 respectively

There is a very large number of significant correlations ($P < 0.01$)

Summary

Significant correlations were found between the majority of the skeletal variables shown in Table 31. This applied in particular to variables that express measurements of angles or dimensions in the same projection plane.

Skeletal and lip variables correlated with variables for tongue position

Significant correlations between skeleton and lip variables on the one hand and variables for tongue position on the other are shown in Table 32. Variables A81 A98 A112 and A126 are not included as they correlate very strongly ($r > 0.85$) to variables A88, A99 A113 and A87 respectively

The significant correlations shown in Table 3 chiefly refer to the relationship between, on the one hand, the shortest distance between the tongue and the hard palate along a perpendicular to the nasion-sella line through pterygo-maxillare (A129) and, on the other skeleton and lip variables that express face height (A88, A89), height of upper lip (A96), the angle between the mandibular and nasion-sella lines (A106), indexes for face width/face height

(A111 A113) and for cranial base depth/face height (A114)

Summary

The significant correlations shown in Table 32 between variables for tongue position and variables for the facial skeleton and lips are in good agreement with the relationships already described between variables for mode of breathing and variables for the facial skeleton and lips (cf. Table 18 p 60)

Thus, it is common for a low tongue position to be found in children with the following skeletal characteristics: large face height, large height of upper lip, large angle between mandibular and nasion-sella lines and small index values for face width/face height and cranial base depth/face height. These skeletal characteristics are the same as those which were shown in Table 12 (p 50) to be characteristic of the children in group 5 i.e. those who underwent adenoidectomy on account of obstructed nose breathing.

Correlations between variables for tongue position

Table 33 presents simple correlations between all pairs of variables for tongue position.

The table shows that the variables for tongue position in relation to the hard and soft palates (A129 and A131 respectively) are strongly intercorrelated ($r = 0.73$)

Results and discussion of multiple regression analyses

CHOICE OF REGRESSANDS

The regressand chosen in order to study which factors influence the mode of breathing is the alternative variable A15 i.e. mouth breathing (yes/no). This variable was preferred to the other mode of breathing variables (A04, A05 and A12) since it was registered by the same observer in all the children.

The regressands chosen to investigate which factors influence nasal airflow before adenoidectomy are the variables for preoperative nasal airflow before (A67) and after (A70) nose drops. The simple correlation analysis has shown that there are strong intercorrelations between the variables for nasal airflow measured at differential pressures of 10, 15 and 20 mm H₂O ($r > 0.97$) before nose drops and consequently that airflow measured at 10 mm H₂O (A67) is fully representative of airflow at 15 and 20 mm H₂O. This also applies to the airflow measurements after nose drops. The measurements at 10 mm H₂O have been chosen because they were obtained in more children than at 15 and 20 mm H₂O owing to the fact that so many of the children had nasal obstructions.

In order to study whether the importance of the regressors for airflow is changed by the administration of nose drops, a separate analysis has been performed with the same regressors as above but with the intraindividual difference between variables A70 and A67 as the regressand (p. 90).

Different combinations of groups of variables have been analyzed in order to study how different groups of variables determine the variation in nasal airflow before as well as after adenoidectomy (p. 91).

The regressands selected for the analysis of dentition variables are the angle between the upper incisors and the nasion-sella line (A46), the angle between the lower incisors and the mandibular line (A48), upper arch width between first molars (A49), overjet (A55), overbite (A56), sagittal relation between upper and lower first molars on right and left (A57 and A58 respectively), the relationship between lower and upper arch width between first molars (A63) and the relationship between height of palatal vault and upper arch width between first molars (A66). These variables were chosen on account of their relationships with the nasal airway variables represented by the anamnesis, adenoid and airflow variables (see Tables 15, 21 and 22, pp. 56, 64 and 65 respectively). The dentition variables (A46, A48, A49 and A63) were also chosen as regressands on account of the significant differences obtained for them in comparisons between the means for control group 1 and group 5 adenoidectomy for obstructed nose breathing (see Table 9 p. 41).

The skeleton variable A107, Angle between the mandibular and nasal lines, has been chosen as a regressand on the same grounds as for the dentition variables above.

NUMBER OF CHILDREN INCLUDED FOR THE REGRESSANDS

The number of children included in each multiple regression analysis has been limited to the number for whom values were obtained for the regressand in question. In the case of the airflow variables, for instance, measurements were not obtained in approximately

15% of the 162 children consequently their values for the regressors were also excluded in the analyses with an airflow variable as regressand.

CHOICE OF REGRESSORS

The regressors chosen for the multiple regression analyses are those listed in Table 1 (pp 13-15) with the following exceptions.

(a) Variables which are closely related to the regressand, e.g. when the regressand was A15 Mouth breathing, the variable for mouth in sleep (A05) was not included.

(b) Variables that could not be registered in a large number of children.

(c) Variables for which a causal influence from the regressand is suspected. For this reason, variables based on information one month after adenoidectomy are with some exceptions excluded if the regressand refers to conditions before adenoidectomy (e.g. A67 A73).

(d) If several variables display very high intercorrelations, one of them has been selected to represent the others. A67 for instance, represents A68 and A69.

(e) Variables have often been excluded if the simple correlation analysis shows that the correlation to the regressand do not reach the 1% level of significance.

The tables only show the variables which are significant at the 5% level. The regression tables also list the regression coefficients and their standard error *t*-values, the partial correlations between the regressand and each of the regressors with allowance made for the other regressors in the table, the total correlation or coefficient of determination (R^2) and the standard deviation of the residuals (R.S.D.)

The multiple regression analyses in this study concern all the children for which each regressand has been registered, at most 162 individuals (see Tables 7 9 11 and 12, pp 38 41 47 and 50 respectively)

One analysis has been made, however on the adenoidectomy children alone. See p 84

REGRESSAND MOUTH BREATHING

In the analysis presented in Table 34 the regressand was variable A15 Mouth breathing, and the regressors were as follows. anamnesis variables A02-03 A16 adenoid variables A26 A29-30 A32-36, A38-41 dentition variables A49 A55 A60 airflow variables A67 A70 and skeleton variables A80 A82-83 A87-95 A100-102, A104-106 A109-110 A112-118 A121-126 (for definitions see Table 1 pp 13-15) The regressors which proved to be significant at the 5% level were introduced in the following order: A16, A40, A41, A109, A83, A55

SUBSTITUTION OF MISSING VALUES FOR REGRESSORS

In the multiple regression analyses, missing values have been replaced by the mean for the regressor in question.

PRINCIPLES FOR THE PRESENTATION OF MULTIPLE REGRESSION ANALYSES

A specified list of the variables concerned is given in the account of each regression analysis. Stepwise regression analysis was performed and

Results

According to this regression analysis, the clinical assessment of enlarged adenoids (A16) and the preoperative size of adenoids in relation to sagittal depth of the bony nasopharynx (A40) are the two most important determinants of mouth breathing.

The coefficient of determination for the regressors included ($R^2=0.74$) is entirely satisfactory.

The variables having regression coefficients which are highly significant ($P<0.001$) have the expected sign.

Results and discussion of multiple regression analyses

CHOICE OF REGRESSANDS

The regressand chosen in order to study which factors influence the mode of breathing is the alternative variable A15 i.e. mouth breathing (yes/no). This variable was preferred to the other mode of breathing variables (A04 A05 and A12) since it was registered by the same observer in all the children.

The regressands chosen to investigate which factors influence nasal airflow before adenoidectomy are the variables for preoperative nasal airflow before (A67) and after (A70) nose drops. The simple correlation analysis has shown that there are strong intercorrelations between the variables for nasal airflow measured at differential pressures of 10, 15 and 20 mm H₂O ($r > 0.97$) before nose drops and consequently that airflow measured at 10 mm H₂O (A67) is fully representative of airflow at 15 and 20 mm H₂O. This also applies to the airflow measurements after nose drops. The measurements at 10 mm H₂O have been chosen because they were obtained in more children than at 15 and 20 mm H₂O owing to the fact that so many of the children had nasal obstructions.

In order to study whether the importance of the regressors for airflow is changed by the administration of nose drops, a separate analysis has been performed with the same regressors as above but with the intraindividual difference between variables A70 and A67 as the regressand (p. 90).

Different combinations of groups of variables have been analyzed in order to study how different groups of variables determine the variation in nasal airflow before as well as after adenoidectomy (p. 91).

The regressands selected for the analysis of dentition variables are the angle between the upper incisors and the nasion sella line (A46), the angle between the lower incisors and the mandibular line (A48), upper arch width between first molars (A49), overjet (A55), overbite (A56), sagittal relation between upper and lower first molars on right and left (A57 and A58 respectively), the relationship between lower and upper arch width between first molars (A63) and the relationship between height of palatal vault and upper arch width between first molars (A66). These variables were chosen on account of their relationships with the nasal airway variables represented by the anamnesis, adenoid and airflow variables (see Tables 15, 21 and 22, pp. 56, 64 and 65 respectively). The dentition variables (A46, A48, A49 and A63) were also chosen as regressands on account of the significant differences obtained for them in comparisons between the means for control group 1 and group 5, adenoidectomy for obstructed nose breathing (see Table 9, p. 41).

The skeleton variable A107, Angle between the mandibular and nasal lines, has been chosen as a regressand on the same grounds as for the dentition variables above.

NUMBER OF CHILDREN INCLUDED FOR THE REGRESSANDS

The number of children included in each multiple regression analysis has been limited to the number for whom values were obtained for the regressand in question. In the case of the airflow variables, for instance, measurements were not obtained in approximately

separate regression analysis was made for these two groups using the same set of variables and procedure as in the analysis above.

The results, presented in Table 35 display good agreement with those for the main analysis in Table 34 except that variable A 16, representing the clinical assessment of enlarged adenoids, does not appear because almost all the children in the adenoid groups presented enlarged adenoids. The coefficient of determination is thereby markedly reduced to $R^2=0.34$

Discussion

Out of a total of 162 children in this study 67 were mouth breathers, 1 belonging to the controls and 66 to the adenoidectomy groups (cf. Table 7 p 38). It should be emphasized, however, that two potential control children were transferred to the adenoidectomy groups on account of obstructed nose breathing (see p 12).

It is therefore hardly surprising that variables A16 and A40-41 which represent size of adenoids, constitute the most important group of factors for determining why certain children breath through the mouth and others through the nose.

Large adenoids can thus be interpreted as causing mouth breathing. The frequency with which mouth breathing was caused by adenoids in the population is difficult to determine from the present study since there is an overrepresentation of the adenoidectomy groups in relation to the control groups, which comprise only 1% of the population of Örebro. Furthermore, children with nasal obstruction have been excluded from the original control material.

Enlarged adenoids are said by Brash (1929) and Nertt (1939) to be the main cause of mouth breathing. Leech (1958) has reported that adenoids caused mouth breathing in 13% of 500 children, of whom 19% were mouth breathers. Reed (1963) has maintained that adenoids is the most common cause of naso-

pharyngeal obstruction with mouth breathing as a consequence.

The opposite opinion—that nasal obstruction is rarely caused by adenoids—has been voiced by James & Hastings (1932), while Ballard & Gwynne-Evans (1958) have reported that flaccidity of the oropharyngeal musculature or swelling of the anterior nasal mucosa is more frequently responsible for mouth breathing in children than adenoidal enlargement. Steele (1968) also holds that nasal obstruction is not always due to adenoid or tonsil hypertrophy.

The variable for swollen nasal mucosa (A18) has not been included among the regressors in the present analysis, which means that any effect on the regressand of such swelling as a consequence of adenoids will have been attributed to the regressors for size of adenoids. At the same time, the simple correlation analysis showed that swollen nasal mucosa is weakly correlated to mouth breathing ($r=0.19$). Furthermore, the overrepresentation of children with adenoids in the adenoidectomy groups may help to explain why swollen nasal mucosa appears to have so little to do with mouth breathing.

The next most important variable in the regression equation after size of adenoids for determining the mode of breathing is A109 which represents the sagittal depth of the bony nasopharynx. This variable serves to represent the skeleton variables that express various dimensions in the nasopharyngeal region. The observed relationship prompts the conclusion that even children with large adenoids may have an adequate nasal airway if the nasopharynx is large and that consequently such children are not obliged to become mouth breathers. The effect of adenoid size on mode of breathing can thus be judged to be dependent on the size of the nasopharynx. This is also indicated by the relationships represented in Fig. 24 in which zones I and II have been delimited in an approximate way so that the former is dominated by mouth breathers and the latter by nose breathers, while both modes of breathing are represented to the same extent

Table 34 *Regressand. A15 Mouth breathing*

Regressor	Coefficient	Std. error	t-value	Partial corr
Constant	1.6390	0.4153	3.95	—
A16 Enlarged adenoids	0.4444	0.0710	6.26 *	0.45
A40 Preop. size of ad.	0.0156	0.0026	6.06	0.44
A41 Postop. size of ad.	-0.0088	0.0025	-3.50	-0.27
A55 Overjet	0.0231	0.0107	2.16	0.17
A83 Nose width	-0.0287	0.0131	-2.19	-0.17
A109 ba-s-pm	-0.0147	0.0041	-3.58	-0.28

$R^2=0.74$ R.S.D. =0.25

An interesting finding is that variable A16 by itself has the coefficient of determination $R^2=0.63$ (cf Table 14 p 55). In other words, size of adenoids counts for most of the total coefficient of determination. It will also be seen that the clinical assessment of size of adenoids has a little higher correlation to mouth breathing than size of adenoids assessed and measured on lateral cephalometric radiographs.

The variables that are highly significant ($P < 0.001$) in this regression analysis and which represent size of adenoids (A16 A40-41) dominate the analysis and by themselves have a high coefficient of determination $R^2=0.70$. The appearance of variable A41 is difficult to interpret as it represents size of adenoids in relation to sagittal depth of the bony nasopharynx after adenoidectomy whereas the regressand—A15 Mouth breathing—refers to conditions before the operation. A conceivable interpretation is that the more of the adenoids

that was removed at adenoidectomy the greater was the previous propensity to breathe through the mouth. In other words, it is conceivable that adenoidectomy was more radical in children with particularly large adenoids.

Variable A109 which represents sagittal depth of the bony nasopharynx, also appears to play some part in determining mouth breathing since it has a partial correlation coefficient of -0.28.

The other variables included in the regression equation are A83 Nose width above alae nasi, and A55 Overjet. Both these are only almost significant ($P < 0.05$).

Thus, it appears that mouth breathing occurs in the first place frequently in children with large adenoids and a small sagittal depth of nasopharynx.

Since it has been shown that almost all the mouth breathers in the present study belonged to groups 4 and 5 (cf Table 7 p 38), a

$R^2=0.34$ R.S.D. =0.32

Summary

This multiple regression analysis has shown that mouth breathing occurs frequently in children with large adenoids and a small nasopharynx in the sagittal plane. For the children in this study mouth breathing is largely explained as a consequence of the size of adenoids and the size of the bony nasopharynx.

REGRESSAND: NASAL AIRFLOW PREOPERATIVELY BEFORE NOSE DROPS

In the analysis presented in Table 36 the regressand was variable A67 Nasal airflow measured before nose drops preoperatively at a differential pressure of 10 mm H₂O and the regressors were as follows. anamnesis variables A02-03 A06, A18 adenoid variables A20, A21 A26, A29 A32, A35 A38 A40 dentition variables A44-49 A51 A53 A55-56, A59-61 A63 A66 skeletal variables A80 A82-83 A87-89 A91-95 A100-103 A106, A109-110, A113 A118, A120-125 (for definitions see Table 1 pp 13-15) The regressors were introduced in the following order A20, A92, A18, A118, A55 A44 A06

Results and discussion

The relationship between the regressand (A67) and the variable for size of adenoids (A20) is also shown diagrammatically in Fig. 25. It will be seen from the figure that nasal airflow is lowest for large adenoids and highest for small or no adenoids. A study of the regression lines shows that size of nasopharynx is of little importance for airflow if the adenoids are large or very large. The change in airflow with increasing nasopharyngeal space is greatest in the middle group—small or moderate adenoids. The differences between the slopes of these regression lines are almost significant ($P < 0.05$).

A reasonable interpretation of this diagram is that the size of the nasopharynx is of little

Fig. 25 Diagram showing the influence of adenoid size (A20) on the relationship between nasal airflow before nose drops before adenoidectomy (A67) and depth of nasopharynx in the sagittal plane (A92). Adenoid size has been arranged in three groups. 1 no adenoids; 2, small or moderate adenoids; 3 large or very large adenoids. The values of each child are marked by plot.

It will be seen that nasal airflow is lowest for large adenoids and highest for small or no adenoids. A regression line is given for each adenoid group showing the relationship between the regressand airflow (A67) and the regressor depth of nasopharynx in the sagittal plane (A92). The slope and position of the regression lines were determined with the computer. The diagram indicates that larger nasopharynx is of little importance for the airflow if the adenoids are large or very large. Airflow changes most with increasing nasopharyngeal space in the middle group—small or moderate adenoids.

importance for airflow if the adenoids are large and impede the passage of air. If there are no adenoids, airflow is again largely unaffected by the size of the nasopharynx because this does not then greatly determine the passage of air. Thus it is only in children with small or moderate adenoids that the size of the nasopharynx is of essential importance for nasal airflow.

The regressors included in the regression equation as determinants of A67 Airflow at a

Fig 24 Diagram showing mode of breathing (A15) in relation to size of adenoids (A40) and depth of nasopharynx in the sagittal plane (A109). The values of each child are marked by a plot. Zone I is dominated by mouthbreathers, zone II by nosebreathers both modes of breathing occur to the same extent in the intermediate zone

in the intermediate zone. This figure reproduces the primary information presented in the regression table namely that variables A109 and

A40 have large determinative values vis-à-vis mouth breathing.

The view that the effect of adenoid size on mode of breathing can be said to be dependent on the size of the nasopharynx has previously been expressed by Bernfeld (1929) Schüller (1929) Emslie, Massler & Zwemer (1952), Ricketts (1954) Goldman & Bachman (1958) and Lubarth (1960).

Of the other regressors in the regression equation (A83 and A55) the variable for nose width above alae nasi (A83) can also be said to represent the size of the nasal airway. A causal relationship appears probable between the size of the nasal airway and mode of breathing.

As a regressor in the regression equation, variable A55 Overjet, is to be regarded as representing the variables for dimensional relationships between the upper and lower jaws (see the regression analysis with A55 as regressand $p > 100$). The relationship between variable A55 and mode of breathing can be interpreted in part as a parallel phenomenon to the sagittal relationship between the upper and lower jaws and in part as a causal relationship. This means that a large overjet is frequent among children who are mouth breathers. It should be noted, however that this relationship is uncertain as the partial correlation coefficient is only 0.17 and no more than almost significant ($P < 0.05$).

R² 0.32; R.A.D. 6.00.

Fig. 21 p. 30) The low value of R^2 should be seen in relation to the large error of method for variable A70. This error amounts to 28% of the variance for all the children in the study (cf. Table 5 p. 29), which means that one cannot expect a higher value of R^2 than 0.72. The observed value should therefore be seen in relation to this maximum, i.e. (0.32/0.72) 100 or 44% as an indication of the determinative value of the regressors in this regression analysis.

Size of adenoids as expressed by variable A20 is shown by this analysis to be the most important determinant of airflow at a differential pressure of 10 mm H₂O after nose drops as well. The coefficient of determination with this variable alone amounts to 0.23. The relationship between size of adenoids and nasal airflow is negative (cf. Table 26 p. 73) which indicates, as expected, that airflow is low when adenoids are large.

The positive relationship between airflow after nose drops (A70) and the degree of prognathism in the lower jaw (A103) can be interpreted as indicating that facial types with little prognathism frequently have a lower nasal airflow. It is conceivable, however, that this relationship is also influenced by a small posterior upper face height. Evidence to this effect is to be found in the significant positive simple correlation coefficients between variable A70 and the variables for degree of prognathism in the upper (A102) and lower (A103) jaws ($r=$

0.28 and 0.34 respectively cf. Table 30 p. 77).

This regression analysis thus reveals a relationship between airflow at a differential pressure of 10 mm H₂O after nose drops on the one hand and, on the other, the variables that express the degree of prognathism in the upper and lower jaws (A102 and A103 respectively).

The variable for face width (A80) also displays a relationship with airflow after nose drops (A70). This can be interpreted as a consequence of the strongly significant correlations between A80 and the variables for posterior choanal width (A100) and volume of bony nasopharynx (A101), i.e. $r=0.43$ and 0.46 respectively (cf. Table 31 p. 78).

This analysis thus indicates that the regressors included in the regression equation express a relationship between the regressand on the one hand and, on the other, regressors that each represent different groups of closely related variables.

It is worth noting that the regression analysis gives only a few variables with significant correlations to variable A70 whereas the simple correlation analysis gave a large number.

Summary

This regression analysis shows that, in this material, nasal airflow at a differential pressure of 10 mm H₂O after nose drops is influenced in the first place by size of adenoids. Other factors of importance in this respect appear to be the degree of prognathism and face width.

differential pressure of 10 mm H₂O before nose drops display only a moderate coefficient of determination $R^2=0.40$. It should be emphasized however that variable A67 has a large irregular error of method. As will be seen from Table 5 (p. 29) the error of method accounts for 30% of the variance for all the children in the study which means that one cannot expect R^2 to be higher than 0.70. The observed value should therefore be seen in relation to this maximum, i.e. $(0.40/0.70) \times 100$ or just under 60% as an indication of the determinative value obtained with the regressors considered in this analysis.

Size of adenoids as represented by the variable A20 proves to be the most important variable but by itself gives a relatively low coefficient of determination $R^2=0.20$ (see Table 26 p. 73). It is conceivable that it occupies such a prominent position because the adenoidectomy children are overrepresented in relation to the controls.

The skeletal variables A92 and A118 which represent sagittal depth of the bony nasopharynx, display the next strongest relationships with airflow before nose drops (A67) indicating that the greater the depth of the nasopharynx the greater the airflow.

The variable for swollen nasal mucosa (A18) also displays a strong—negative—relationship with airflow before nose drops (A67).

The other regressors in the regression equation are only significant at the 5% level, i.e. overjet (A55), height of corpus mandibulae (A44) and recurrent infections in the ear, nose and throat (A06). As a regressor in the regression equation overjet (A55) is to be regarded as a consequence of mouth breathing and a low airflow rather than as a determinant of the airflow variable A67. Concerning the other two variables in the regression equation—A44 and A06—it is conceivable that their presence is a pure coincidence—in an analysis of sixty regression coefficients it is hardly surprising that two artefact coefficients reach the 5% level of significance. This interpretation is supported by the non-significant simple correla-

tion coefficients between A67 on the one hand and A44 and A06 on the other ($r=0.07$ and -0.18 respectively).

Summary

This regression analysis shows that the measurements of airflow in the present children at a differential pressure of 10 mm H₂O before nose drops (A67) are affected in the first place by size of adenoids, sagittal depth of the bony nasopharynx and the degree of swelling in the nasal mucosa. Furthermore size of nasopharynx is shown to be of little importance for airflow in children with very large adenoids that impede the passage of air; this also applies in children with no adenoids, since the passage of air is then sufficient regardless of the size of the nasopharynx. It is only in the presence of small and moderate adenoids that size of nasopharynx is of essential importance for the magnitude of the nasal airflow.

REGRESSAND: NASAL AIRFLOW PREOPERATIVELY AFTER NOSE DROPS

In the analysis presented in Table 37 the regressand was variable A70. Nasal airflow measured at a differential pressure of 10 mm H₂O after nose drops, and the regressors were the same as in the regression analysis with variable A67 as regressand. The following regressors, given here in the order of introduction, proved to be significant at the 1% level: A20, A103, A80.

Results and discussion

The regressors included in the regression equation as determinants of airflow at a differential pressure of 10 mm H₂O after nose drops (A70) have only a low coefficient of determination $R^2=0.32$. It should be noted however that these airflow measurements were difficult to reproduce exactly (the coefficient for the correlation between the initial value A70 and the value one month later A76 was 0.75 of

Fig. 26. Distribution of children by age of the angle IL_1/NSL . The difference between the means for the adenotomized group and the controls is entirely ascribable to the low values in adenotomized group 5.

be induced to follow the instructions. This analysis did not reveal any essential changes and does not call for any modification of the interpretations presented above.

In a further multiple regression analysis with the interindividual difference between variables A70 and A67 as the regressand and the same regressors as before, none of the regressors in the equations tabulated above obtained significant correlation coefficients. This means that the regressors which are significant for variable A67 but not for A70 as regressand and vice versa can be substituted with correlated regressors (cf. variable A80 in the regression analysis with A70 as regressand) and that the regressors which proved significant in one of the analyses are on the verge of being significant in the other.

EXPLANATORY VALUE OF DIFFERENT GROUPS OF REGRESSANDS THAT EXPRESS NASAL AIRFLOW

In the simple correlation analyses and multiple regression analyses, many regressors displayed significant relationships with the airflow regressands. In order to analyze the relative importance of different groups of regressors, these were divided into variables for age and sex, other anamnesis variables, adenoid, dentition and skeleton variables. These groups were then introduced into the analysis in different

COMPARISON BETWEEN REGRESSANDS NASAL AIRFLOW BEFORE AND AFTER NOSE DROPS

A comparison between the regression analyses in which the regressands were nasal airflow at a differential pressure of 10 mm H₂O before (A67) and after (A70) nose drops respectively shows that size of adenoids as represented by variable A20 is the most important determinant for the magnitude of nasal airflow.

The variable for swollen nasal mucosa (A18) only features in the analysis in which airflow before nose drops (A67) is the regressand. A plausible explanation for this is that the nasal mucosa is decongested after nose drops (A70).

Skeletal variables that reflect the size of the nasopharynx are represented in both analyses, by variables A92 and A118 before nose drops (A67) and by variable A80 after nose drops (A70).

Concerning the other skeletal variables, degree of prognathism as represented by A103

features only in the analysis with variable A70 as the regressand.

The dentition variables displayed weak correlations with airflow in both analyses.

The variables for year of birth and sex (A02 and A03) did not prove significant in either of these regression analyses.

In view of the fact that missing values for variables A67 and A70 amounted to approximately 15% and chiefly referred to the adenoidectomy groups (groups 4 and 5 cf. Table 11 p. 47) a separate regression analysis was made to determine whether the absence of the values has appreciably affected the conclusions drawn from the regression analyses in which these variables served as regressands. In this regression analysis the missing airflow values were treated as 0 on the grounds that in most of the cases in which airflow could not be measured, the reason was total obstruction of the nasopharynx. The analysis does, however, include a few cases that were expected to show normal airflow but where the child could not

The grouping variable (A79) is also included as a regressor in this regression equation. The negative relationship indicates that retroclination of upper incisors was more common among the children in the groups with a high number i.e. the adenoidectomy groups (4 and 5).

The variable for upper arch width between first molars (A49) is also included in the regression equation as a determinant of variable A46 in this case the relationship is positive.

Length of upper lip (A96) shows a negative most significant relationship in the regression equation with the angle between the upper incisors and the nasion-sella line.

Thus, retroclination of upper incisors in relation to the nasion-sella line appears to be frequent in children with a small lower face height, large overbite, long upper lip a small rath for the angle s-n-as and a narrow upper arch between first molars such retroclination was also more common among the present adenoidectomy children than among the controls.

Discussion

Of the regressors that are included in the regression equation, the variables A56, Overbite, A90, Anterior lower face height, and A102, Angle between sella turcica—nasion—subnasale, are highly significant ($P < 0.001$). The group variable A79 is significant at the 1% level. The other regressors—A49 Upper arch width between first molars, and A96 Height of upper lip—are significant at the 5% level. The relationships between the regressand and the various regressors must be considered to have an underlying cause in common.

It is conceivable, however that there is a causal relationship in the negative correlation between the regressand and regressor A96 retroclination of the upper incisors being regarded as a consequence of increased lip pressure from a long upper lip and altered muscle balance when the mouth is held open in mouth breathing.

Fig. 28 Distribution of children by size of the angle IL/ML. The difference between the means for the adenoidectomy group and the controls is entirely ascribable to the low values in adenoidectomy group 5.

The determinative value of the grouping variable (A79) is probably a reflection of determination from variables for mode of breathing, adenoids and airflow. It is therefore particularly interesting that regressor A79 indicates that retroclination of the upper incisors is more frequent among the adenoidectomy children than among the controls.

The circumstance that about 81% of the adenoidectomy children—all of whom had large adenoids—were mouth breathers suggests that mouth breathers have more retro-

Fig. 27 Relationship between the regressand A46 and the regressors A56 size of vertical overbite and A50 lower face height. The values of each child are marked by a plot. Separate regression lines for different values for lower face height have been obtained with the computer. The diagram indicates that the relationship between the regressand A46 and the regressor A56 is appreciable only for low values of A50 lower face height. It is worth noting that the children with high values for lower face height include the largest number of mouthbreathers.

sequences—though always with age and sex first and other anamnesis variables last—in order to study the resultant increment to the coefficient of determination (see Table 38).

Table 38 shows that the explanatory value of age and sex is slight and that the adenoid variables and the skeleton variables each have a higher coefficient of determination than the dentition variables with respect to the regressands A67 and A70. In the case of regressands A73 and A76 the skeleton variables have the highest explanatory value while the adenoid and dentition variables have the same coefficient.

The anamnesis variables appear to be important for regressands A67 and A73 i.e. only before nose drops.

Taken together the variables for age and sex

and the adenoid, dentition and skeleton variables display approximately the same explanatory value for each of the airflow variables.

REGRESSAND ANGLE BETWEEN UPPER INCISORS AND NASION SELLA LINE

In the analysis presented in Table 39 the regressand was variable A46 Angle between upper incisors and nasion-sella line and the regressors were as follows: anamnesis variables A02-03 A15-16 adenoid variable A20 dentition variables A49 A55-56 A60-61 group variable A79 airflow variables A67 A70 skeleton variables A88 A90-92 A96-97 A101-102 A106-108. The regressors included in the regression equation were introduced in the following order: A102, A79 A56 A90 A49 and A96.

The distribution of the control and adenoidectomy children with respect to the regressand is shown in Fig. 26.

Results

The regressors included in the regression equation as determinants of the regressand A46 have a moderate coefficient of determination $R^2=0.39$. If one also includes all the regressors enumerated above that are not significant at the 5% level the coefficient of determination increases to 0.45.

The variables that are highly significant or significant ($P<0.001$ $P<0.01$ respectively) have the expected sign.

The strongest relationships with this regressand concern the variables that express lower face height (A90) and overbite (A56). These relationships indicate that retroclination of upper incisors in relation to the nasion-sella line is frequently found in children with a small lower face height and large overbite (cf. Fig. 27).

The variable for the angle s-n-s (A102) displays the next strongest relationship with the measure of retroclination (A46).

grouping variable (A79) is also included as a regressor in this regression equation. The negative relationship indicates that inclination of upper incisors was more common among the children in the groups with a number i.e. the adenoidectomy groups (4 and 5).

Variable for upper arch width between molars (A49) is also included in the regression equation as a determinant of variable A46. In case the relationship is positive.

Height of upper lip (A96) shows a negative and significant relationship in the regression equation with the angle between the upper incisors and the nasion-sella line.

Retraction, retroclination of upper incisors in relation to the nasion-sella line appears to be present in children with a small lower face angle, large overbite, long upper lip, a small angle for the angle s-n-x and a narrow upper arch. Between first molars, such retroclination also more common among the present adenoidectomy children than among the controls.

Regression

Regressors that are included in the regression equation, the variables A56, Overbite,

Anterior lower face height, and A102, Angle between sella turcica—nasion—subnasale are highly significant ($P < 0.001$). The grouping variable A79 is significant at the 1% level. The other regressors—A49 Upper arch height between first molars, and A96 Height of upper lip—are significant at the 5% level. Relationships between the regressand and various regressors must be considered to find an underlying cause in common.

It is conceivable, however that there is a causal relationship in the negative correlation between the regressand and regressor A96, retroclination of the upper incisors being regarded as a consequence of increased lip pressure from a long upper lip and altered muscle tone when the mouth is held open in mouth

Fig. 38. Distribution of children by size of the angle IL/JML . The difference between the means for the adenoidectomy group and the controls is entirely ascribable to the low values in adenoidectomy group 5.

The determinative value of the grouping variable (A79) is probably a reflection of determination from variables for mode of breathing, adenoids and airflow. It is therefore particularly interesting that regressor A79 indicates that retroclination of the upper incisors is more frequent among the adenoidectomy children than among the controls.

The circumstance that about 81% of the adenoidectomy children—all of whom had large adenoids—were mouth breathers suggests that mouth breathers have more retro-

$R^2 = 0.48$ R.S.D. = 5.14

clined incisors. Similar results have been reported by Leech (1958) in a study which showed that Angle $\text{C} \perp \text{II} 2$ is more frequent than $\text{C} \perp \text{II} 1$ in individuals with large adenoids. Thus the present results do not support the frequently expressed opinion that mouth breathers usually have proclined upper incisors, e.g. Angle (1907), Strang (1933), Bowen & Balyeat (1934), McCoy (1941), Johnson (1942), Ballenger & Ballenger (1943), Massler, Poncher & Schour (1945), Giacometti (1947), Subtelny (1954), Negus (1955), Duyzeng (1963) and Moyers (1963).

Summary

This multiple regression analysis shows that retroclined upper incisors are frequently found in children with a small lower face height, large overbite, long upper lip, small value for the angle $s-n$ and a narrow upper arch and that such retroclination was more common among the present adenoidectomy children than among the controls. The relationships between the regressand and the various regressors may be regarded as having an underlying cause in common. There may also be a causal negative almost significant relationship between inclination of upper incisors and length of upper lip, a conceivable explanation being that retroclination of the upper incisors is a consequence of increased lip pressure from a long upper lip and an altered muscle balance when the mouth is held open in mouth breathing.

REGRESSAND: ANGLE BETWEEN LOWER INCISORS AND MANDIBULAR LINE

In the analysis presented in Table 40 the regressand was variable A48: Angle between lower incisors and mandibular line, and the regressors were as follows: anamnestic variable A02-03, A15-16 adenoid variable A20, dentition variables A49, A55-56, A60, growth variable A79, airflow variables A67, A70, skeleton variables A88, A90-92, A96-97, A101, A103, A106-108. The regressors were introduced in the following order: A107, A15, A55.

The distribution of the control and adenoidectomy children with respect to the regressand is shown in Fig. 28.

Results

The regressors included in the regression equation as determinants of the regressand (A48) display a moderate coefficient of determination, $R^2 = 0.48$. If one also includes all the regressors enumerated above that are not significant at the 5% level, the coefficient is increased to 0.58. The variables that are highly significant ($P < 0.001$) display the expected sign.

Variable A107, Angle between mandibular and nasal lines, displays the strongest relationship with the regressand in this analysis. By itself this variable has a coefficient of determination $R^2 = 0.28$ (see Table 23, p. 67). The relationship indicates that children with a large

Fig. 29 Diagram showing the relationship between the regressand A48 and the regressor A107 angle between the mandibular and nasal lines, nosebreathers and mouthbreathers being denoted with different symbols. The sizes of each child are marked by plot. Separate regression lines for the two modes of breathing have been obtained with the computer. The diagram indicates that the regression line for nosebreathers lies higher than for mouthbreathers and that variable A48 decreases with increasing values of variable A107.

angle between the mandibular and nasal lines commonly display retroclination of the lower incisors.

The next strongest relationship with the regressand concerns variable A15 Mouth breathing. Thus, the mouth breathers in this study more frequently had retroclined lower incisors (cf. Fig. 29).

Variable A55 Overjet, is also included as a regressor in this regression equation. The relationship indicates that the children with a large overjet frequently had proclined lower incisors.

The regression analysis thus shows that retroclination of the lower incisors in relation to the mandibular line is common among children with a large angle between the mandibular and nasal lines, small overjet and mouth breathing.

Discussion

All the regressors included in the regression equation are highly significant ($P < 0.001$).

The strong relationship between inclination of the lower incisors and the angle between the mandibular and nasal lines should be seen in the first place as a parallel to the circumstance that this inclination was measured in relation to the mandibular line.

The relationship between retroclination of the lower incisors and mouth breathing can further be interpreted as a consequence of the lip muscles acting on the lower incisors when the mouth is held open in mouth breathing. This may possibly lead to increased tension in the orbicularis oris muscle, resulting in posterior pressure against the incisors because the tendon plates attaching this muscle at the angles of the mouth are held back in turn by the buccinator zygomaticus major and caninus muscles (Petrén 1948).

A low tongue position in mouth breathing (see Table 19 cf. Subtelny 1954 Holik, 1957 Ricketts, 1958 a), with the tongue possibly held withdrawn as well, may also have contributed to retroclination of the lower incisors due to reduced tongue pressure against the lingual surface of these teeth.

The positive relationship between overjet (A55) and the regressand (A48) reflects the circumstance that these two variables have the same underlying mechanism.

Summary

This multiple regression analysis shows that retroclination of the lower incisors is common among children who have a large angle between the mandibular and nasal lines, a small overjet and mouth breathing.

The retroclination of lower incisors in the present children is considered in part to be a consequence of posterior rotation of the lower jaw under the influence of the lip muscles and/or reduced tongue pressure against the lingual surface of the lower incisors when the tongue is held low in mouth breathing, and in part to reflect constitutional factors.

Table 40 *Regressand A48 Angle between lower incisors and mandibular line*

Regression coefficients, their std. error level of significance (marked with asterisks), partial correlation coefficients, the total correlation coefficient (R^2), and the standard deviation of the residuals (R.S.D.), in an analysis of 23 regressors

Regressor	Coefficient	Std. error	t value	Partial corr
Constant	113.1500	2.6688	42.40	—
A15 Mouth breathing	-5.0374	0.9946	-5.06	-0.42
A55 Overjet	1.3701	0.3.86	4.17	0.36

clined incisors. Similar results have been reported by Leech (1958) in a study which showed that Angle CI II 2 is more frequent than CI II 1 in individuals with large adenoids. Thus the present results do not support the frequently expressed opinion that mouth breathers usually have proclined upper incisors e.g. Angle (1907) Strang (1933) Bowen & Balyeat (1934) McCoy (1941) Johnson (1942) Ballenger & Ballenger (1943) Massler Poncher & Schour (1945) Giacometti (1947) Subtelny (1954) Negus (1954) Duyzing (1963) and Moyers (1963).

Summary

This multiple regression analysis shows that retroclined upper incisors are frequently found in children with a small lower face height, large overbite, long upper lip, small value for the angle s-n-as and a narrow upper arch and that such retroclination was more common among the present adenoidectomy children than among the controls. The relationships between the regressand and the various regressors may be regarded as having an underlying cause in common. There may also be a causal negative almost significant relationship between inclination of upper incisors and length of upper lip, a conceivable explanation being that retroclination of the upper incisors is a consequence of increased lip pressure from a long upper lip and an altered muscle balance when the mouth is held open in mouth breathing.

REGRESSAND ANGLE BETWEEN LOWER INCISORS AND MANDIBULAR LINE

In the analysis presented in Table 40 the regressand was variable A48 Angle between lower incisors and mandibular line, and the regressors were as follows: anamnesis variables A02-03 A15-16 adenoid variable A20 dentition variables A49 A55-56 A60 group variable A79 airflow variables A67 A70 skeleton variables A88 A90-92 A96-97 A101 A103 A106-108. The regressors were introduced in the following order: A107 A15 A55.

The distribution of the control and adenoidectomy children with respect to the regressand is shown in Fig. 28.

Results

The regressors included in the regression equation as determinants of the regressand (A48) display a moderate coefficient of determination, $R^2 = 0.48$. If one also includes all the regressors enumerated above that are not significant at the 5% level the coefficient is increased to 0.58. The variables that are highly significant ($P < 0.001$) display the expected sign.

Variable A107 Angle between mandibular and nasal lines displays the strongest relationship with the regressand in this analysis. By itself this variable has a coefficient of determination $R^2 = 0.28$ (see Table 23 p. 67). The relationship indicates that children with a large

A113 lo-lo/a-gn	0.0697	0.0336	2.07	0.19

R^2 0.51 R.S.D. 1.72

As will be seen from Table 42, the coefficient of determination is reduced to $R^2=0.35$

In this regression equation, the regressors are the same skeleton variables as before plus A82, Nose width over alae nasi.

According to both these regression analyses, the size of the variable for upper arch width between first molars (A49) appears to be determined chiefly by the skeleton and dentition variables (cf. Fig. 31)

Thus, a narrow upper arch between the first molars appears to be common among children with a small nasopharynx, a long, narrow face, a short, crowded upper jaw and a large angle between the upper and lower jaws, i.e. between the nasal and mandibular lines.

Discussion

The regressors that are significant at the 1% and 0.1% levels in the regression equation are dominated by variables representing the size of the upper jaw. The value of these variables as determinants of upper arch width between

the first molars is to be regarded as a parallel phenomenon between regressand and regressors rather than as a causal relationship.

Concerning the skeleton variables denoting the volume of the body nasopharynx and an index for face width/face height, it is again difficult to see a causal relationship between these and the variable for upper arch width between the first molars. These relationships should also be interpreted as parallel phenomena in the sense that a narrow upper jaw is common among children with a narrow type of face and little space in the nasopharynx. A significant positive relationship between face width and arch width has been demonstrated previously by Lundström & Lysell (1953), Linder Aronson & Bäckström (1960), Linder Aronson (1963), Solow (1966) and Slagvold (1969).

The significant relationships demonstrated in the simple correlation analyses for upper arch width between first molars on the one hand and, on the other, the angles between the mandibular line and the nasal (A107) and maxil-

REGRESSAND: UPPER ARCH WIDTH BETWEEN FIRST MOLARS

In the analysis presented in Table 41 the regressand was variable A49 Upper arch width between first molars, and the regressors were as follows: anamnesis variables A02-03 A13-14 adenoid variables A20 A32 A38 A40 dentition variables A46-48 A53-54 A56-57 A61 group variable A79 airflow variables A67 A70 A73 A76 skeleton variables A80

A82, A85-87 A91-92 A94 A100-103 A105-107 A113 A121 A123 and A126. The regressors were introduced in the following order: A61 A101 A107 A57 A53 and A113.

The distribution of the control and adenoidectomy children with respect to the regressand is shown in Fig. 30.

Results

The regressors included in the regression equation as determinants of upper arch width give a coefficient of determination $R^2 = 0.51$.

Volume of bony nasopharynx (A101) is the variable in this regression analysis that has the strongest relationship with width of upper arch between first molars. By itself, however, this variable has a coefficient of determination of no more than 0.17 (see Table 23 p. 67).

Variable A61 Space difference of upper arch, displays the next strongest relationship with width of upper arch.

The variable for the sagittal relationship between the mesial surfaces of the upper and lower first molars on the right side (A57) also appears to be related to the width of the upper arch between the first molars.

Furthermore, the regression analysis shows that children with a narrow upper arch between the first molars have a large angle between the mandibular and nasal lines (A107).

The relationship between length (A53) and width (A49) of upper arch (see Table 20, p. 63) is also demonstrated in this regression analysis, which shows that the former variable is a determinant of the latter.

Another finding is that the index for face width face height (A113) appears to be of some importance in determining the width of the upper arch between the first molars.

In order to study to what extent the dentition variables included as regressors contributed to the determination of regressand A49, a second analysis was made with the same regressand and the same regressors apart from the dentition variables.

Table 41. *Regressand. A49 Upper arch width between first molars*

Regression coefficients, their std. error, level of significance (marked with asterisks), partial correlation coefficients, the total correlation coefficient (R^2), and the standard deviation of the residuals (R.S.D.), in an analysis of 40 regressions

Regressor	Coefficient	Std. error	t-value	Partial corr
Constant	27.7980	4.2970	6.47	—
A53 Length of upper arch	0.1982	0.0724	2.74	0.24

A113 lo-to-a-ga	0.0697	0.0336	2.07	0.19

R^2 0.51 R.S.D. 1.72

As will be seen from Table 42, the coefficient of determination is reduced to $R^2=0.35$.

In this regression equation, the regressors are the same skeleton variables as before plus A82, nose width over alae nasi.

According to both these regression analyses, the size of the variable for upper arch width between first molars (A49) appears to be determined chiefly by the skeleton and dentition variables (cf. Fig. 31).

Thus, a narrow upper arch between the first molars appears to be common among children with a small nasopharynx, a long, narrow face, a short, crowded upper jaw and a large angle between the upper and lower jaws, i.e. between the nasal and mandibular lines.

Discussion

The regressors that are significant at the 1% and 0.1% levels in the regression equation are dominated by variables representing the size of the upper jaw. The value of these variables as determinants of upper arch width between

the first molars is to be regarded as a parallel phenomenon between regressand and regressors rather than as a causal relationship.

Concerning the skeleton variables denoting the volume of the bony nasopharynx and an index for face width/face height, it is again difficult to see a causal relationship between these and the variable for upper arch width between the first molars. These relationships should also be interpreted as parallel phenomena in the sense that a narrow upper jaw is common among children with a narrow type of face and little space in the nasopharynx. A significant positive relationship between face width and arch width has been demonstrated previously by Lundström & Lysell (1953), Linder Aronson & Bäckström (1960), Linder Aronson (1963) Solow (1966) and Sjaegvold (1969).

The significant relationships demonstrated in the simple correlation analyses for upper arch width between first molars on the one hand and, on the other, the angles between the mandibular line and the nasal (A107) and nasion-

Fig. 31 Diagram showing the relationship between the regressand A49 and the regressors A101 volume of nasopharynx and A107 the angle ML/NL. Separate regression lines for different values of the angle ML/NL have been obtained with the computer. The diagram indicates that the relationship between the regressand A49 and the regressor A101 is appreciable only for low values of the angle ML/NL. It is worth noting that the children with high values for the angle ML/NL include the largest number of mouthbreathers.

sella lines (A106)—cf Table 23 p 67—are represented in the regression equation by variable A107. The relationship indicates that children with a narrow upper arch more frequently display large angles between the mandibular line and the nasal and nasion-sella lines.

These relationships are supported by the highly significant correlation ($r=0.26$ $P<0.001$) in the simple correlation analysis (cf Table 20 p 63) between variable A49 and variable A56 Overbite, since the latter variable has been shown to be related with the variables representing the angles between the mandibular line and the nasal and nasion-sella lines (A107 and A106 respectively cf Table 23 p 67).

It is particularly noteworthy that the significant correlations obtained in the simple correlation analysis between A49 and the airflow variables A70, A73 and A76 (cf Table 22

p 65) have not appeared in the present regression equation as determinants of upper arch width between first molars. Since highly significant correlations have been found between the variables for airflow after nose drops (A70 and A76) and variable A101 Volume of bony nasopharynx ($r=0.32$ and 0.37 respectively $P<0.001$ cf Table 30 p 77) and since the latter variable is one of the regressors in the present regression equation it has probably served to reflect the relationship between A49 and the airflow variables.

The determinants in the regression equation do not include any of the adenoid variables either i.e. A20, A32, A38 and A40. According to the regression analyses for mouth breathing (A15 p 84) and airflow (A67 p 87) these two factors are influenced in the first place by size of adenoids and size of nasopharynx. Since the variables for size of adenoids have

Fig. 32. Distribution of children by size of overjet. The distribution appears asymmetric in the adenoidectomy group as well as in the control group—neither group has many children with overjet ≤ 5 mm.

lars is largely determined in these children by the skeleton and dentition variables. A narrow upper arch is common among children with a small nasopharynx, a long, narrow face, a narrow nose, a short, crowded upper jaw and a large angle between the nasal and mandibular lines.

According to this analysis, a narrow upper arch between the first molars in these children is in the first place a parallel phenomenon to their long, narrow type of face with a small nasopharynx and narrow nose. This, however, does not rule out the possibility of a causal relationship between upper arch width and adenoids, with mouth breathing and a low tongue position as a result. This can be investigated best by follow-up studies after adenoidectomy.

REGRESSAND: OVERJET

In the analysis presented in Table 43 the regressand was variable A55 Overjet, and the regressors were as follows: anamnesis variables A02–03 A15 adenoid variable A20 dentition variables A53 A57–58 A65 airflow variables A67 A70 group variable A79 skeleton variables A85–87 A91 A96, A105 A126–127 tongue position variable A129. The regressors were introduced in the following order: A105 A126 A57 A53 and A15.

The distribution of the control and adenoidectomy children with respect to the regressand is shown in Fig. 32.

Summary

The multiple regression analyses show that the width of the upper arch between the first mo-

Summary

This multiple regression analysis shows that large overjet is common among children with a large value for the angle ss-n-sm, a long upper arch, large sagittal length of the roof of the nasal cavity and a postnormal relation between the upper and lower first molars, and mouth breathing.

The size of overjet in the present children appears to be largely a parallel phenomenon to the sagittal relationship between the upper and lower jaws as well as to the sagittal length of the roof of the nasal cavity and of the upper arch.

REGRESSAND: OVERBITE

In the analysis presented in Table 44 the regressand was variable A56, Overbite and the regressors were as follows. anamnesis variables A02-03 A10 dentition variables A49 A60 A63 airflow variables A67 A70 skeleton variables A80 A85-87 A89 A91 A94 A101 A106-107 A116 A121 A126-127 The regressors were introduced in the following order A63 A02, A116 and A127.

The distribution of the control and adenoidectomy children with respect to the regressand is shown in Fig. 33.

Results

The regressors included in the regression equation as determinants of the size of overbite display a moderate coefficient of determination.

Results

The regressors included in the regression equation as determinants of the size of overjet have a moderate coefficient of determination $R^2 = 0.46$. If one also includes all the regressors enumerated above that are not significant at the 5% level, the coefficient of determination is increased only to 0.52. The variables that are significant at the 1% and 0.1% levels display the expected sign.

In this regression analysis the strongest relationship with size of overjet is displayed by variable A105 Angle subspinale-nasion-supramentale. By itself this variable has a coefficient of determination $R^2 = 0.25$ (cf Table 23 p. 66). The next strongest relationship with overjet is displayed by variable A57 Sagittal relation between the mesial surfaces of upper and lower first molars on the right side.

Variable A53 Length of upper arch, also appears to be important for determining the size of overjet as does variable A126, which expresses the sagittal length of the roof of the nasal cavity.

The regression analysis also indicates that variable A15 Mouth breathing, is of some importance for size of overjet but this relationship is significant only at the 5% level.

Large overjet thus appears to be common among children with large values for the angle subspinale-nasion-supramentale, a long upper arch, large sagittal length of the roof of the nasal cavity, a postnormal relationship between the upper and lower first molars and mouth breathing.

Discussion

The variables that are significant at the 1% or 0.1% level in the regression equation represent jaw relationships in the sagittal plane (A105 A57) a sagittal dimension on the roof of the nasal cavity (A126) and length of upper arch (A53).

The relationships between regressand A55 Overjet, and these four regressors are to be

regarded as parallel phenomena in that the size of overjet is influenced by sagittal displacement in the relationship between upper and lower jaw (A105 A57) or the size of the sagittal depth of the upper jaw (A126 A53).

A possible explanation for the almost significant relationship ($P < 0.05$) between variable A15 Mouth breathing, and large overjet is that the sagittal relationship between the upper and lower jaws increases in connection with posterior rotation of the lower jaw in mouth breathing.

The frequently expressed opinion that individuals who breathe through the mouth have a large overjet as a consequence of proclined upper incisors (Angle, 1907 Strang 1933 McCoy 1941 Ballenger & Ballenger 1943 Giacometti 1947 Negus 1955 Duyzing 1963) is not supported by this regression analysis since the variables that express the inclination of the upper and lower incisors (A46 and A48 respectively) have not featured as regressors. Instead, the results indicate that the children who were mouth breathers and who underwent adenoidectomy had more retroclined upper and lower incisors than the controls. The differences between the adenoidectomy and control groups in this respect are 6.6 and 7.3 respectively and are significant at the 0.1% level (cf Table 9 p. 41).

The regression analyses in which the regressands are the variables for the inclination of the upper and lower incisors (A46 and A48 respectively) also indicate that the adenoidectomy children had a greater degree of retroclination.

If the variable for overjet is regarded as an expression for the sagittal relationship between the upper and lower jaws frontally as well as laterally and if the size of overjet increases in mouth breathing the results obtained appear to support the opinion put forward by James & Hastings (1932) namely that mouth breathing accentuates the postnormal relationship in persons with a natural postnormal tendency. It has not been found, on the other hand, that mouth breathers usually have

Fig. 34 Distribution of children in accordance with the sagittal relationship between the mesial surfaces of the right first molars in the upper and lower jaws. The distribution is the same in the adenoidectomy group and the controls.

15 ± 56), which showed a highly significant correlation ($r = -0.40$, $P < 0.001$) for the relationship between overbite and year of birth. These results fully agree with earlier reports by Serpel (1946), Baume (1950) and Moores (1959). The increase in overbite with increasing age can be explained in terms of the difference in crown height between the deciduous and

permanent incisors. Overbite involving the incisors thus increases in absolute terms from the deciduous to the permanent dentition but is not changed in relative terms (Moores 1959). Approximately 35% of the children in this study had deciduous incisors.

No significant relationships were found for the airflow regressors in this regression analysis.

Summary

This multiple regression analysis shows that a small overbite is common among children with crossbite or a tendency to crossbite, a small value for the relationship between anterior upper and total face height, and a small posterior upper face height. A small overbite was also found more frequently among the younger children.

The size of overbite in the children in this study is considered to be a parallel phenomenon to crossbite or a tendency to crossbite and to the size of upper face height.

The increase in overbite with increasing age is considered to be a consequence of the difference in crown height between the deciduous and permanent incisors.

REGRESSAND: SAGITTAL RELATIONSHIP BETWEEN MESIAL SURFACES OF UPPER AND LOWER RIGHT FIRST MOLARS

In the analysis presented in Table 45 the regressand was variable A57 Sagittal relationship between mesial surfaces of upper and lower right first molars, and the regressors were as follows. anamnesis variables A07–03 dentition variables A48 A55 airflow variables A67 A70 group variable A79 skeleton variables A85 A105 A113 tongue-position variable A19 The regressors were introduced in the following order A55 A113 A85 A105 and A03.

The distribution of the control and adenoidectomy children with respect to the regressand is shown in Fig. 34.

$R^2 = 0.33$ If one also includes all the regressors enumerated above that are not significant at the 5% level the coefficient increases only to 0.41. The variables that are significant at the 1% and 0.1% levels display the expected sign.

The regressor that displays the strongest relationship with overbite is variable A63 which expresses the relationship between the widths of the lower and upper arches between the first molars. The coefficient of determination for this variable alone is $R^2 = 0.23$ (cf Table 20 p 63).

The next strongest relationship with overbite is displayed by variable A116 which expresses the relationship between anterior upper face height (A89) and total face height (A88). In the simple correlation analysis, anterior upper face height (A89) showed a significant correlation ($r = 0.34$) with overbite (A56) but total face height (A88) did not (cf Table 23 p 66). The relationship obtained for the index variable in the regression analysis is therefore to be regarded in the first place as a reflection of the relationship between anterior upper face height and overbite.

The regression analysis also shows that year of birth (A02) is involved in determining the size of overbite. The negative almost significant relationship indicates that the children in this study with a low year of birth i.e. relatively high age, have a larger overbite than the younger children.

Variable A127 which represents the approximate vertical dimension of the body of the sphenoid bone, is also shown by the regression analysis to be related to size of overbite. The simple correlation analysis indicated that this variable is closely related ($r = 0.67$) with variable A94 Posterior upper face height (cf Table 31 p 78). The almost significant relationship indicated in the regression analysis between variable A127 and overbite can therefore also be regarded as a reflection of the relationship between posterior upper face height and overbite.

A small overbite is thus common in this study among children with a large value for

the relationship between the widths of the lower and upper arches, i.e. crossbite or a tendency to crossbite, a small value for the relationship between anterior upper and total face height, a small posterior upper face height and a high year of birth i.e. low age.

Discussion

Of the regressors that are included in the regression equation the variable A63 Crossbite, is highly significant ($P < 0.001$). The variable A116 Index for the relationship between upper anterior and total face height is significant at the 1% level. The other regressors—A02, Year of birth, and A127 Approximate vertical dimension of the body of the sphenoid bone—are significant at the 5% level.

According to this regression analysis, the size of overbite is largely determined by variable A63 i.e. crossbite or a tendency to crossbite.

The relationship between crossbite and small overbite can be interpreted as a parallel phenomenon. If the lower jaw displays an anterior position in relation to the upper jaw there will be a greater probability of crossbite as well as small overbite. This explanation, however, does not seem to apply to the present material, as cases with large adenoids and mouthbreathing have a tendency towards postnormal rather than prenormal occlusion. Further studies seem necessary before an explanation can be found for the relationship shown.

The skeleton variables for the relationship between upper anterior and total face height (A116) posterior face height (A94) and approximate vertical dimension of the body of the sphenoid bone (A127) appear to be of some importance as determinants of the size of overbite. The relationship between the regressand and these regressors is to be regarded as a parallel phenomenon rather than as a causal relationship.

The regression equation also includes the variable for year of birth (A02). This is in line with the simple correlation analysis (cf Table

Fig. 34 Distribution of children in accordance with the sagittal relationship between the mesial surfaces of the right first molars in the upper and lower jaws. The distribution in the adenoidectomy group and the controls.

15 p. 56) which showed a highly significant correlation ($r = -0.40$, $P < 0.001$) for the relationship between overbite and year of birth. These results fully agree with earlier reports by Selpel (1946), Baume (1950) and Moorees (1959). The increase in overbite with increasing age can be explained in terms of the difference in crown height between the deciduous and

permanent incisors. Overbite involving the incisors thus increases in absolute terms from the deciduous to the permanent dentition but is not changed in relative terms (Moorees 1959). Approximately 35% of the children in this study had deciduous incisors.

No significant relationships were found for the airflow regressors in this regression analysis.

Summary

This multiple regression analysis shows that a small overbite is common among children with crossbite or a tendency to crossbite, a small value for the relationship between anterior upper and total face height, and a small posterior upper face height. A small overbite was also found more frequently among the younger children.

The size of overbite in the children in this study is considered to be a parallel phenomenon to crossbite or a tendency to crossbite and to the size of upper face height.

The increase in overbite with increasing age is considered to be a consequence of the difference in crown height between the deciduous and permanent incisors.

REGRESSAND: SAGITTAL RELATIONSHIP BETWEEN MESIAL SURFACES OF UPPER AND LOWER RIGHT FIRST MOLARS

In the analysis presented in Table 45 the regressand was variable A57 Sagittal relationship between mesial surfaces of upper and lower right first molars, and the regressors were as follows: anamnesis variables A02-03 dentition variables A48, A55 airflow variables A67 A70 group variable A79 skeleton variables A85 A105 A113 tongue-position variable A179. The regressors were introduced in the following order: A55 A113 A85 A105 and A03.

The distribution of the control and adenoidectomy children with respect to the regressand is shown in Fig. 34.

A113 lo-to/n-gn	-0.1316	0.0462	-2.85	-0.25

$R^2 = 0.27$ R.S.D. = 2.29

Results

The regressors included in the regression equation as determinants of the sagittal relationship between the mesial surfaces of the upper and lower right first molars have a low coefficient of determination $R^2 = 0.27$. If one also includes all the regressors enumerated above that were not significant at the 5% level the coefficient of determination is increased to $R^2 = 0.30$.

Variable A85 which represents the length of the anterior part of the cranial base appears to be the most important determinant in this regression analysis but has a very weak coefficient of determination by itself $R^2 = 0.05$ (cf. Table 23 p. 66). Since variables A85 and A57 both represent dimensions in the sagittal plane, the relationship obtained in this regression analysis can be interpreted as an example of a connection between skeleton and dentition variables in the same projection plane.

The variable that displays the next strongest relationship with regressand A57 is A105 which represents the angle subspinale-nasion-supramentale. The relationship between the regressand and variable A113 Index for face width/face height indicates that children with high index values have a small sagittal distance, i.e. a postnormal tendency between the mesial surfaces of the upper and lower right first molars.

The sex variable (A03) displays an almost significant relationship with regressand A57. It

was thus more common for the girls in this study to have a small sagittal distance between the mesial surfaces of the upper and lower right first molars, i.e. a tendency towards a postnormal molar relationship in the girls and/or a prenormal relationship in the boys.

The almost significant relationship between overjet (A55) and regressand A57 in this regression analysis corresponds to the relationship in the analysis with A55 as regressand.

A small sagittal distance, i.e. a postnormal tendency between the mesial surfaces of the upper and lower right first molars, thus appears to be common among children with a large anterior cranial base length, large values for the angle subspinale-nasion-supramentale, large overjet, large index values for face width/face height and among girls.

Discussion

In spite of the low coefficient of determination ($R^2 = 0.27$) one regressor displays highly significant relationships ($P < 0.001$), namely variable A85, while two are significant ($P < 0.01$) namely A105 and A113. The regressors A03 and A55 are almost significant ($P = 0.05$). As is often the case with a low coefficient of determination the relationships between regressors and regressand are difficult to interpret.

A possible explanation for the correlations between variables A105 and A55 on the one hand and regressand A57 on the other is that

Fig. 35 Distribution of children in accordance with the sagittal relationship between the mesial surfaces of the left first molars in the upper and lower jaws. The distribution is the same for the adenoidectomy group and the controls.

a large sagittal difference in the anterior region is associated with a small difference in the sagittal plane between the mesial surfaces of the upper and lower first molars. This would be in line with the significant correlation described by Seipel (1946) between a postnormal molar relationship and increased overjet. This relationship should be interpreted, not as a causal connection between the regressors and

the regressand, but as a parallel phenomenon.

Difficulty in measuring the regressand is sometimes responsible for a low coefficient of determination. In the present case, however, the measurements were made on models and the error of method vis-à-vis the biological relationships is probably small. A possible explanation for the variations in the regressands is that certain variables have not been registered, e.g. mesial displacement of first molars as a result of premature loss of the deciduous molars.

Summary

This multiple regression analysis suggests that a postnormal relationship between the mesial surfaces of the right first molars is common among children with a large anterior cranial base length, large values for the angle $ss-n-sm$, large overjet, large index values for face width/face height and among girls.

As is often the case with a low coefficient of determination, the relationships between regressand and regressors are difficult to interpret. The almost significant relationship between a postnormal molar relationship and large overjet is nevertheless considered to be a parallel phenomenon.

REGRESSAND SAGITTAL RELATIONSHIP BETWEEN MESIAL SURFACES OF UPPER AND LOWER LEFT FIRST MOLARS

In the analysis presented in Table 46 the regressand was variable A58 Sagittal relationship between mesial surfaces of upper and lower left first molars, and the regressors were as follows: anamnesis variables A02-03 dentition variable A55 airflow variables A67 A70-group variable A79 skeleton variables A90 A106-107 tongue-position variable A129. Only one regressor A55 was introduced.

The distribution of the control and adenoidectomy children with respect to the regressand is shown in Fig. 35.

Table 45 *Regressand A57 Sagittal relation between the mesial surfaces of the right upper and lower first molars*

Regression coefficients, their std error level of significance (marked with asterisks), partial correlation coefficients, the total correlation coefficient (R^2) and the standard deviation of the residuals (R.S.D.) in an analysis of 11 regressors

Regressor	Coefficient	Std error	t value	Partial corr

A113 lo-lo/n-gn	-0.1316	0.0462	-2.85	-0.25

$R^2=0.27$ R.S.D.=2.29

Results

The regressors included in the regression equation as determinants of the sagittal relationship between the mesial surfaces of the upper and lower right first molars have a low coefficient of determination $R^2=0.27$. If one also includes all the regressors enumerated above that were not significant at the 5% level the coefficient of determination is increased to $R^2=0.30$.

Variable A85 which represents the length of the anterior part of the cranial base, appears to be the most important determinant in this regression analysis but has a very weak coefficient of determination by itself $R^2=0.05$ (cf Table 23 p. 66). Since variables A85 and A57 both represent dimensions in the sagittal plane the relationship obtained in this regression analysis can be interpreted as an example of a connection between skeleton and dentition variables in the same projection plane.

The variable that displays the next strongest relationship with regressand A57 is A105 which represents the angle subspinale-nasion-supramentale. The relationship between the regressand and variable A113 Index for face width/face height indicates that children with high index values have a small sagittal distance, i.e. a postnormal tendency between the mesial surfaces of the upper and lower right first molars.

The sex variable (A03) displays an almost significant relationship with regressand A57. It

was thus more common for the girls in this study to have a small sagittal distance between the mesial surfaces of the upper and lower right first molars, i.e. a tendency towards a postnormal molar relationship in the girls and/or a prenormal relationship in the boys.

The almost significant relationship between overjet (A55) and regressand A57 in this regression analysis corresponds to the relationship in the analysis with A55 as regressand.

A small sagittal distance, i.e. a postnormal tendency between the mesial surfaces of the upper and lower right first molars, thus appears to be common among children with a large anterior cranial base length, large values for the angle subspinale-nasion-supramentale, large overjet, large index values for face width/face height and among girls.

Discussion

In spite of the low coefficient of determination ($R^2=0.27$) one regressor displays highly significant relationships ($P < 0.001$) namely variable A85 while two are significant ($P < 0.01$) namely A105 and A113. The regressors A03 and A55 are almost significant ($P < 0.05$). As is often the case with a low coefficient of determination the relationships between regressors and regressand are difficult to interpret.

A possible explanation for the correlations between variables A105 and A55 on the one hand and regressand A57 on the other is that

Fig. 35 Distribution of children in accordance with the sagittal relationship between the mesial surfaces of the left first molars in the upper and lower jaws. The distribution is the same for the adenoidectomy group and the controls.

a large sagittal difference in the anterior region is associated with a small difference in the sagittal plane between the mesial surfaces of the upper and lower first molars. This would be in line with the significant correlation described by Serpel (1946) between a postnormal molar relationship and increased overjet. This relationship should be interpreted, not as a causal connection between the regressors and

the regressand, but as a parallel phenomenon.

Difficulty in measuring the regressand is sometimes responsible for a low coefficient of determination. In the present case, however the measurements were made on models and the error of method vis-à-vis the biological relationships is probably small. A possible explanation for the variations in the regressands is that certain variables have not been registered, e.g. mesial displacement of first molars as a result of premature loss of the deciduous molars.

Summary

This multiple regression analysis suggests that a postnormal relationship between the mesial surfaces of the right first molars is common among children with a large anterior cranial base length, large values for the angle $ss-o-sm$, large overjet, large index values for face width/face height and among girls.

As is often the case with a low coefficient of determination, the relationships between regressand and regressors are difficult to interpret. The almost significant relationship between a postnormal molar relationship and large overjet is nevertheless considered to be a parallel phenomenon.

REGRESSAND: SAGITTAL RELATIONSHIP BETWEEN MESIAL SURFACES OF UPPER AND LOWER LEFT FIRST MOLARS

In the analysis presented in Table 46 the regressand was variable A58. Sagittal relationship between mesial surfaces of upper and lower left first molars, and the regressors were as follows: anamnestic variables A02-03 dentition variable A55 airflow variables A67 A70 group variable A79 skeleton variables A90, A106-107 tongue-position variable A129. Only one regressor A55 was introduced.

The distribution of the control and adenoidectomy children with respect to the regressand is shown in Fig. 35.

Table 45 *Regressand A57 Sagittal relation between the mesial surfaces of the right upper and lower first molars*

Regression coefficients, their std. error, level of significance (marked with asterisks), partial correlation coefficients, the total correlation coefficient (R^2), and the standard deviation of the residuals (R.S.D.) in an analysis of 11 regressors

Regressor	Coefficient	Std. error	t value	Partial corr.
Constant	33.4320	6.5187	5.13	—
A03 Sex	-1.0749	0.4374	-2.46	-0.22
A55 Overjet	-0.3645	0.1571	-2.32	-0.21
A85 n-s	-0.6629	0.0755	-3.48	-0.30
A105 ss-n-gn	-0.3133	0.1032	-3.03	-0.27
A113 lo-lo/n-gn	-0.1316	0.0462	-2.85	-0.25

$R^2 = 0.27$ R.S.D. = 2.29

Results

The regressors included in the regression equation as determinants of the sagittal relationship between the mesial surfaces of the upper and lower right first molars have a low coefficient of determination $R^2 = 0.27$. If one also includes all the regressors enumerated above that were not significant at the 5% level, the coefficient of determination is increased to $R^2 = 0.30$.

Variable A85, which represents the length of the anterior part of the cranial base, appears to be the most important determinant in this regression analysis but has a very weak coefficient of determination by itself, $R^2 = 0.05$ (cf. Table 23 p. 66). Since variables A85 and A57 both represent dimensions in the sagittal plane, the relationship obtained in this regression analysis can be interpreted as an example of a connection between skeleton and dentition variables in the same projection plane.

The variable that displays the next strongest relationship with regressand A57 is A105, which represents the angle subspinale-nasion supramentale. The relationship between the regressand and variable A113, index for face width/face height, indicates that children with high index values have a small sagittal distance, i.e. a postnormal tendency between the mesial surfaces of the upper and lower right first molars.

The sex variable (A03) displays an almost significant relationship with regressand A57. It

was thus more common for the girls in this study to have a small sagittal distance between the mesial surfaces of the upper and lower right first molars, i.e. a tendency towards a postnormal molar relationship in the girls and/or a prenormal relationship in the boys.

The almost significant relationship between overjet (A55) and regressand A57 in this regression analysis corresponds to the relationship in the analysis with A55 as regressand.

A small sagittal distance, i.e. a postnormal tendency between the mesial surfaces of the upper and lower right first molars, thus appears to be common among children with a large anterior cranial base length, large values for the angle subspinale-nasion supramentale, large overjet, large index values for face width/face height and among girls.

Discussion

In spite of the low coefficient of determination ($R^2 = 0.27$), one regressor displays highly significant relationships ($P < 0.001$), namely variable A85, while two are significant ($P < 0.01$), namely A105 and A113. The regressors A03 and A55 are almost significant ($P < 0.05$). As is often the case with a low coefficient of determination, the relationships between regressors and regressand are difficult to interpret.

A possible explanation for the correlations between variables A105 and A55 on the one hand and regressand A57 on the other is that

Fig. 36 Distribution of children in accordance with the index does for the relationship between the widths of the lower and upper arches between the first molars. The distribution is the same for the adenoidectomy group and the controls.

The next strongest relationship with the regressand is displayed by variable A96 Length of upper lip. This relationship is positive and indicates that a long upper lip is common among children whose lower arch is wide in relation to the upper arch.

The regression analysis also indicates an almost significant relationship between mouth breathing (A15) and a narrow upper arch in relation to the lower arch.

Variable A92, Sagittal depth of bony nasopharynx, also shows some relation with the size of the index for lower and upper arch width between first molars.

Thus, the regression analysis shows that a narrow upper arch in relation to the lower arch, i.e. crossbite or a tendency to crossbite, is common among children with a small overbite, long upper lip, small sagittal depth of bony nasopharynx and mouth breathing.

Discussion

The regressors included in the regression equation as determinants of the index for lower and upper arch width between first molars comprise variables that express height dimensions in the dentition (A56) and face (A96) as well as variables for mouth breathing (A15) and size of nasopharynx (A92). A highly significant relationship is displayed for regressor A56 ($P < 0.001$).

The strong relationship between overbite (A56) and crossbite (A63) has already been interpreted as a parallel phenomenon (in the regression equation with A56 as regressand, p. 102).

Variable A96 Height of upper lip can be said to represent variables associated with face height. As shown by the simple correlation analysis (cf. Table 31 p. 78), A96 correlates particularly strongly ($r = -0.61$, $P < 0.001$) with the variable for total face height (A88). The relationship between the present regressand and skeletal variables that express face height should be interpreted as a parallel phenomenon, in that high face height often occurs in

pression analysis. By itself, this variable has a coefficient of determination $R = 0.43$ (cf. Table 20, p. 63). The relationship indicates that a wide lower arch in relation to the upper arch, i.e. crossbite or a tendency to crossbite, tends to be accompanied by a small overbite.

Table 46 *Regressand A58 Sagittal relation between the mesial surfaces of the left upper and lower first molars*

Regression coefficients, their std. error, level of significance (marked with asterisks), partial correlation coefficients, the total correlation coefficient (R^2), and the standard deviation of the residuals (R.S.D.) in an analysis of 10 regressors

Regressor	Coefficient	Std error	t value	Partial corr
Constant	2.9563	0.5318	5.59	—
A55 Overjet	-0.5827	0.1487	-3.91	-0.33

$R^2 = 0.11$ R.S.D. = 2.41

Results

Regressor A55 Overjet is included in the regression equation as a determinant of the sagittal relationship between the mesial surfaces of the upper and lower left first molars and gives a coefficient of determination of only $R^2 = 0.11$. The relationship for this regressor is highly significant ($P < 0.001$). If one also includes all the regressors enumerated above that are not significant at the 5% level, the coefficient of determination is increased only to $R^2 = 0.19$.

The significant correlation between variable A55 and regressand A58 corresponds to the almost significant relationship between A55 and regressand A57 in the preceding regression analysis.

A small sagittal distance i.e. a postnormal tendency between the mesial surfaces of the upper and lower left first molars thus appears to be common among children with a large overjet.

Discussion

The relationships demonstrated in the regression analysis with variable A57 as regressand can also be expected when the regressand is variable A58 though there may well be some difference between the variables in view of the local migration of teeth that may have occurred in the molar regions of either jaw on the right and left sides.

REGRESSAND INDEX FOR LOWER AND UPPER ARCH WIDTHS BETWEEN FIRST MOLARS

In the analysis presented in Table 47 the regressand was variable A63 Index for lower and upper arch widths between first molars, and the regressors were as follows: anamnesis variables A02-04 A12-16 adenoid variables A20 A32 A35 A38 A40 dentition variables A48 A56 airflow variables A67 A70 A73 A76 group variable A79 skeleton variables A91-92, A96 A102, A121 A124. The regressors were introduced in the following order: A56 A15 A96 and A92.

The distribution of the control and adenoidectomy children with respect to the regressand is shown in Fig. 36.

Results

The regressors included in the regression equation as determinants of the index for the relationship between lower and upper arch widths between first molars display a moderate coefficient of determination $R^2 = 0.38$. If one also includes all the above regressors that are not significant at the 5% level the coefficient of determination increases to $R^2 = 0.47$. The highly significant and the significant variables ($P < 0.001$ $P < 0.01$ respectively) display the expected sign.

Variable A56 Overbite, displays the strongest relationship with the regressand in this re-

Fig. 37. Distribution of children in accordance with the index values for the relationship between height of palatal vault and width of upper arch between first molars. The distribution is the same for the adenoidectomy group and the controls.

Zerner 195 Ballard & Gwynne Evans, 1958).

The opinion of Ricketts (1958 & 1968) that crossbite is often found in mouth breathers receives support from these results.

Summary

The multiple regression analysis shows that crossbite or a tendency to crossbite frequently occurs in children with a small overbite long upper lip small sagittal depth of nasopharynx and mouth breathing. All relationships between the regressand and the regressors are inter-

preted primarily as parallel phenomena, though a causal relationship between mouth breathing and the presence of crossbite is considered probable.

REGRESSAND: INDEX FOR HEIGHT OF PALATAL VAULT AND UPPER ARCH WIDTH BETWEEN FIRST MOLARS

In the analysis presented in Table 48 the regressand was variable A66 Index for height of palatal vault and upper arch width between first molars, and the regressors were as follows: anamnesis variables A02-03 A05 A12, A15 dentition variable A61 airflow variables A67 A70 group variable A79 skeleton variables A80-81 A84 A86-90 A96-98 A100, A128 A113 interaction variable $A67 \times A15$. The regressors were introduced in the following order: A02, A88 A15 A67 and A81.

The distribution of the control and adenoidectomy children with respect to the regressand is shown in Fig. 37.

Results

The regressors included in the regression equation as determinants of the index for height of palatal vault and upper arch width between first molars have a satisfactory coefficient of determination, $R^2=0.57$.

The variable for year of birth (A02) appears to be the most important determinant in this regression analysis for the size of the index for height of palatal vault and upper arch width between first molars. By itself this variable has a coefficient of determination $R^2=0.38$ (cf Table 15 p. 56) and is highly significant ($P < 0.001$).

The next strongest relationship with the regressand is displayed by the variable for mouth breathing (A15) but this is only significant at the 1% level ($P < 0.01$). The relationship indicates that children who breathe through the mouth often have a high palatal vault and/or a narrow upper arch.

Table 47 *Regressand A63 Relationship between lower and upper arch widths between first molars*

Regression coefficients, their std. error level of significance (marked with asterisks), partial correlation coefficients, the total correlation coefficient (R^2), and the standard deviation of the residuals (R.S.D.), in an analysis of 26 regressions

Regressor	Coefficient	Std. error	t value	Partial corr
Constant	91.7540	6.2360	14.72	—
A15 Mouth breathing	1.7938	0.8148	2.20	0.20
A56 Overbite	-1.5065	0.2807	-5.37	-0.44
A92 pm-ba	-0.2430	0.1132	-2.15	-0.19
A96 Height of upper lip	0.5428	0.1757	3.09	0.27

$R^2 = 0.38$ R.S.D. = 4.03

conjunction with crossbite or a tendency to crossbite.

The variable for mouth breathing (A15) also features in the regression equation as a determinant of the index for lower and upper arch width between first molars but is only significant at the 5% level. It is probable that the determinative value of this variable also includes an influence from the adenoid, airflow and tongue-position variables. The simple correlation analyses demonstrated significant relationships between mouth breathing on the one hand and, on the other, the adenoid variable A20 ($r = 0.66$ $P < 0.001$ cf Table 16 p 57) the preoperative airflow variable A67 ($r = -0.30$ $P < 0.001$ cf Table 17 p 59) and the tongue position variable A129 ($r = 0.47$ $P < 0.001$ cf Table 19 p 62).

The relationship demonstrated in the regression equation between mouth breathing (A15) and crossbite (A63) has already been demonstrated in the simple correlation analysis (cf Table 15 p 56). It may be interpreted as a causal relationship and/or as reflecting a common underlying cause.

A causal relationship between mouth breathing and the index for lower and upper arch width between first molars is envisaged as being due to the low position of the tongue in mouth breathing (cf Table 19 p 62). This enables the tongue to exert greater transverse pressure on the lower first molars than on the upper. It is also conceivable that the obstruction of nose breathing tends to inhibit lateral growth of the upper face.

Variable A92, Sagittal depth of nasopharynx, is also included as a regressor in this regression equation and is only significant at the 5% level. Considering that this variable displays strong significant correlations to the majority of skeleton variables that express nasopharyngeal dimensions (Table 31 p 78) it is conceivable that it features in the regression equation as a representative for these nasopharyngeal variables.

The relationship demonstrated in the regression equation between the variable for sagittal depth of nasopharynx and the variable for crossbite can be interpreted as an expression of relationships between skeleton and dentition variables in neighbouring regions and is consequently to be regarded as indicating the same phenomenon.

The size of the index for lower and upper arch width between first molars in the children in this study is interpreted in this multiple regression analysis as a parallel phenomenon to skeleton variables representing face height and dimensions in the nasopharyngeal region and/or as a consequence of mouth breathing and the low tongue position associated with this.

The results thus indicate that crossbite or a tendency to crossbite is often associated with a large face height and mouth breathing. They therefore support the frequently expressed opinion that there is often an association between a narrow upper jaw, a long narrow face and mouth breathing (e.g. Brash 1929 Poncher Schour & Massler 1945 Emslie Massler &

Fig. 37. Distribution of children in accordance with the index for the relationship between height of palatal vault and width of upper arch between first molars. The distribution is the same for the adenotomized group and the controls.

Zwemer 195 Ballard & Gwynne-Evans, 1958).

The opinion of Ricketts (1958 & 1968) that crossbite is often found in mouth breathers receives support from these results.

Summary

The multiple regression analysis shows that crossbite or a tendency to crossbite frequently occurs in children with a small overbite, long upper lip, small sagittal depth of nasopharynx and mouth breathing. All relationships between the regressand and the regressors are inter-

preted primarily as parallel phenomena, though a causal relationship between mouth breathing and the presence of crossbite is considered probable.

REGRESSAND: INDEX FOR HEIGHT OF PALATAL VAULT AND UPPER ARCH WIDTH BETWEEN FIRST MOLARS

In the analysis presented in Table 48 the regressand was variable A66, Index for height of palatal vault and upper arch width between first molars, and the regressors were as follows: anamnestic variables A02-03 A05 A12, A15 dentition variable A61 airflow variables A67 A70 group variable A79 skeleton variables A80-81 A84 A86-90 A96-98 A100, A128, A113 interaction variable A67 \times A15. The regressors were introduced in the following order: A02 A88, A15 A67 and A81.

The distribution of the control and adenotomized children with respect to the regressand is shown in Fig. 37.

Results

The regressors included in the regression equation as determinants of the index for height of palatal vault and upper arch width between first molars have a satisfactory coefficient of determination. $R^2 = 0.57$.

The variable for year of birth (A02) appears to be the most important determinant in this regression analysis for the size of the index for height of palatal vault and upper arch width between first molars. By itself this variable has a coefficient of determination $R^2 = 0.38$ (cf. Table 15 p. 56) and is highly significant ($P < 0.001$).

The next strongest relationship with the regressand is displayed by the variable for mouth breathing (A15) but this is only significant at the 1% level ($P < 0.01$). The relationship indicates that children who breathe through the mouth often have a high palatal vault and/or a narrow upper arch.

Table 48 *Regressand A66 Relationship between height of palatal vault and upper arch width between first molars*

Regression coefficients, their std. error level of significance (marked with asterisks), partial correlation coefficients, the total correlation coefficient (R^2), and the standard deviation of the residuals (R.S.D.), in an analysis of 4 regressors

Regressor	Coefficient	Std. error	t-value	Partial corr
Constant	152.5200	26.9712	5.65	—
A02 Year of birth	-2.6428	0.3366	-7.85	-0.60
A15 Mouth breathing	2.8349	1.0816	2.62	0.24
A67 Preop airflow before nose drops	0.2206	0.1024	2.15	0.20
A88 n-gn	0.2.26	0.1003	2.22	0.21

$R^2 = 0.57$ R.S.D. = 5.00

The regression analysis also displays an all most significant relationship between nasal air flow preoperatively before nose drops (A67) and the regressand. This relationship is positive, pointing to a large airflow for a high palatal vault and/or a narrow upper arch. By including the interaction variable $A67 \times A15$ it was found however that the relationship between A67 and regressand A66 only applies to the children who are nose breathers. On the other hand, the airflow variable A67 appears to be of less importance for mouth breathers if one includes all the other regressors.

The size of the index for height of palatal vault and upper arch width between first molars thus appears to depend in the first place on the age of the child.

This regression analysis also shows that a high palatal vault and/or a narrow upper arch are frequently found in children who breath through the mouth.

Discussion

The strong negative relationship between the regressand and year of birth suggests that the height of the palatal vault increases more with age than the width of the upper arch. This has been demonstrated previously by Franke (1921) and Hellman (1927).

The presence of variable A15 Mouth breathing, as a regressor in this regression equation is to be regarded as a consequence of a high

palate and/or a narrow upper arch rather than as a determinant of regressand A66. In this context, the relationship between arch width and mouth breathing is considered to be more relevant than that between height of palatal vault and mouth breathing (cf Table 15 p. 56). The relationship between mouth breathing and a narrow arch has already been discussed in connection with the regression analysis in which the regressand was variable A49 Upper arch width between first molars (see p. 98).

The results in this regression analysis appear to support the opinion of several authors that children who breath through the mouth often have a narrow upper arch and/or a high palatal vault (e.g. Körbitz, 1910; Izard, 1925; Bowen & Balyeat, 1934; Massier-Poncher & Schour, 1945; Ballard, 1952).

Summary

This multiple regression analysis shows that the size of the index for height of palatal vault and upper arch width between first molars is primarily dependent on the age of the child. It also shows that a high palatal vault and/or a narrow upper arch are often found in mouth breathers. Mouth breathing in these children is to be regarded as a consequence of a high palatal vault and/or a narrow upper arch rather than as a cause of this. In this context the relationship between arch width and mouth breathing is considered more relevant than that between height of palatal vault and mouth breathing.

Fig. 38 Distribution of children by the size of the angle ML/AZ. The difference between the means for the adenoidectomy group and the controls is entirely attributable to the high values in adenoidectomy group 3. It is also worth noting that the control group displays symmetric distributions, whereas that for the adenoidectomy children is skewed.

REGRESSAND: ANGLE BETWEEN MANDIBULAR AND NASAL LINES

In the analysis presented in Table 49 the regressand was variable A107 Angle between mandibular and nasal lines, and the regressors were as follows: anamnesis variables A02, A05-06 A08, A1-16 adenoid variables A20

A29 A32, A38 A40 dentition variables A49 A56 group variable A79 airflow variables A67 A70 A73 A76 skeleton variables A85 A87 A92-93 A96-97 A103 A105 A109 A124 A126 The regressors were introduced in the following order: A96 A105 A97 A70 A124 and A85.

The distribution of the control and adenoidectomy children with respect to the regressand is shown in Fig. 38.

Results

The regressors included in the regression equation as determinants of the angle between the mandibular and nasal lines have a moderate coefficient of determination. $R^2=0.45$. If one also includes all the above regressors that are not significant at the 5% level, the coefficient of determination rises to $R^2=0.63$.

Variable A105 which represents the angle subnasale-nasion-supraorbitale, features in this regression analysis as the most important determinant but, by itself has a very low coefficient of determination. $R^2=0.04$ (cf. Table 31 p 78).

The next strongest relationship with the regressand is displayed by the variable for the angle subnasale-nasion-basion (A124).

The variables for height of upper (A96) and lower lip (A97) are also included as regressors, as is the variable for the length of the anterior part of the cranial base (A85).

Airflow variables as determinants of the size of the regressand are represented in this regression equation by variable A70.

According to this multiple regression analysis, a large angle between the mandibular and nasal lines frequently occurs in children with a large angle ss-n-sm, a small angle ss-n-ba, long upper and lower lips, a short anterior cranial base and small nasal airflow.

Discussion

All the regressors in the regression equation are highly significant ($P<0.001$) with the exception of the airflow variable (A70).

Table 48 *Regressand A66 Relationship between height of palatal vault and upper arch width between first molars*

Regression coefficients, their std. error level of significance (marked with asterisks), partial correlation coefficients, the total correlation coefficient (R^2) and the standard deviation of the residuals (R.S.D.), in an analysis of 24 regressors

Regressor	Coefficient	Std. error	t value	Partial corr
Constant	152.5200	26.9712	5.65	—
A02 Year of birth	-0.6428	0.3366	-7.83	-0.60
A15 Mouth breathing	2.8349	1.0816	2.62	0.24
A67 Preop airflow before nose drops	0.2206	0.1024	2.15	0.20
A88 n-gn	0.2226	0.1003	2.22	0.21

$R^2 = 0.57$ R.S.D. = 5.05

The regression analysis also displays an almost significant relationship between nasal airflow preoperatively before nose drops (A67) and the regressand. This relationship is positive pointing to a large airflow for a high palatal vault and/or a narrow upper arch. By including the interaction variable $A67 \times A15$ it was found however that the relationship between A67 and regressand A66 only applies to the children who are nose breathers. On the other hand the airflow variable A67 appears to be of less importance for mouth breathers if one includes all the other regressors.

The size of the index for height of palatal vault and upper arch width between first molars thus appears to depend in the first place on the age of the child.

This regression analysis also shows that a high palatal vault and/or a narrow upper arch are frequently found in children who breathe through the mouth.

Discussion

The strong negative relationship between the regressand and year of birth suggests that the height of the palatal vault increases more with age than the width of the upper arch. This has been demonstrated previously by Franko (1921) and Hellman (1927).

The presence of variable A15 Mouth breathing, as a regressor in this regression equation is to be regarded as a consequence of a high

palate and/or a narrow upper arch rather than as a determinant of regressand A66. In this context, the relationship between arch width and mouth breathing is considered to be more relevant than that between height of palatal vault and mouth breathing (cf Table 15 p. 56). The relationship between mouth breathing and a narrow arch has already been discussed in connection with the regression analysis in which the regressand was variable A49 Upper arch width between first molars (see p. 98).

The results in this regression analysis appear to support the opinion of several authors that children who breathe through the mouth often have a narrow upper arch and/or a high palatal vault (e.g. K8rbitz, 1910; Izard 1925; Bowen & Balyeat, 1934; Massier, Poncher & Schour 1945; Ballard 1952).

Summary

This multiple regression analysis shows that the size of the index for height of palatal vault and upper arch width between first molars is primarily dependent on the age of the child. It also shows that a high palatal vault and/or a narrow upper arch are often found in mouth breathers. Mouth breathing in these children is to be regarded as a consequence of a high palatal vault and/or a narrow upper arch rather than as a cause of this. In this context the relationship between arch width and mouth breathing is considered more relevant than that between height of palatal vault and mouth breathing.

Fig. 38 Distribution of children by the size of the angle ML/NL. The difference between the means for the adenoidectomy group and the controls is entirely ascribable to the high values in adenoidectomy group 5. It is also worth noting that the control group displays symmetric distribution, whereas that for the adenoidectomy children is J-shaped.

REGRESSAND: ANGLE BETWEEN MANDIBULAR AND NASAL LINES

In the analysis presented in Table 49 the regressand was variable A107 Angle between mandibular and nasal lines, and the regressors were as follows. anamnesis variables A02, A05-06, A08 A12-16 adenoid variables A20

A29 A32, A38 A40 dentition variables A49 A56 group variable A79 airflow variables A67 A70, A73 A76 skeleton variables A85 A87 A92-93 A96-97 A103 A105 A109 A124 A126 The regressors were introduced in the following order A96, A105 A97 A70 A124 and A85

The distribution of the control and adenoidectomy children with respect to the regressand is shown in Fig. 38

Results

The regressors included in the regression equation as determinants of the angle between the mandibular and nasal lines have a moderate coefficient of determination $R^2=0.45$. If one also includes all the above regressors that are not significant at the 5% level the coefficient of determination rises to $R^2=0.63$.

Variable A105 which represents the angle subspinale-nasion-supramentale, features in this regression analysis as the most important determinant but, by itself has a very low coefficient of determination: $R^2=0.04$ (cf Table 31 p 78).

The next strongest relationship with the regressand is displayed by the variable for the angle subspinale-nasion-basion (A124).

The variables for height of upper (A96) and lower lip (A97) are also included as regressors, as is the variable for the length of the anterior part of the cranial base (A85).

Airflow variables as determinants of the size of the regressand are represented in this regression equation by variable A70.

According to this multiple regression analysis, a large angle between the mandibular and nasal lines frequently occurs in children with a large angle ss-n-sm, a small angle ss-n-ba, long upper and lower lips, a short anterior cranial base, and small nasal airflow.

Discussion

All the regressors in the regression equation are highly significant ($P<0.001$) with the exception of the airflow variable (A70).

A70 Preop airflow after nose drops	-0.1377	0.0536	-2.57	-0.20
A85 n-a	-0.4088	0.1163	-3.51	-0.27
A96 Height of upper lip	0.5928	0.1605	3.69	0.28
A97 Height of lower lip	0.4051	0.0989	4.10	0.31
A105 ss-n-sm	0.8107	0.1624	4.99	0.37
A124 ss-n-ba	-0.4575	0.1089	-4.20	-0.31

$R^2=0.45$ R.S.D. = 4.19

The relationships obtained between the regressand and regressors A85 Anterior cranial base length A105 Angle ss-n-sm and A124 Angle ss-n-ba, may be regarded as indicators of the same facial morphology. The negative relationship between the angle ss-n-ba (A124) and the angle between the mandibular and nasal lines (A107) agrees with descriptions of individuals with small values for the angles s-n-sa and s-n-sm (Byörl 1947 Lindegård 1953 Solow 1966 Hasund & Remme 1967).

The relationship between preoperative air flow (A70) and the regressand can be interpreted in part as a reflection of the same underlying cause and in part as an expression for a causal connection.

The latter interpretation reflects the view that the determinative value of A70 probably includes influences from variables for mode of breathing and adenoids as well as the consideration that posterior rotation of the lower jaw is facilitated in mouth breathers. It has been pointed out by Ricketts (1968) that such posterior rotation occurs in mouth breathers because they often hold the head tilted slightly backwards.

Summary

This multiple regression analysis shows that a large angle between the mandibular and nasal lines is often found in children with a large angle ss-n-sm a small angle ss-n-ba long

upper and lower lips, short anterior cranial base and small nasal airflow

The relationships obtained between the regressand and the regressors are considered to have the same underlying mechanism, though a causal connection may be expressed to some extent by the relationship between the regressand and the airflow variable. A large angle between the mandibular and nasal lines in children with a small nasal airflow is explained in this context by the circumstance that posterior rotation of the lower jaw is facilitated in mouth breathers.

ANALYSIS OF THE IMPORTANCE OF TONGUE POSITION FOR CERTAIN DENTITION VARIABLES

The simple correlation analyses showed that there are significant correlations between mouth breathing and large adenoids on the one hand and, on the other the dentition variables A46 Angle between upper incisors and nasion-sella line, A48, Angle between lower incisors and mandibular line, and A49 Upper arch width between first molars cf. Tables 15 and 21 pp 56 and 64

A separate analysis has therefore been made

to investigate whether the relationship between adenoids and these dentition variables can be attributed to the presence of adenoids causing mouth breathing, which leads in turn to a change in tongue position that then affects these dentition variables

The analysis was made on 51 of the children in the present study selected as having small or extremely large adenoids. The group with small adenoids comprised the controls whose size of adenoids according to variable A32 was less than the mean for the controls in group 1 i.e. $A32 < 73.64\%$ (cf. Table 10 p. 45). The group with extremely large adenoids comprised the adenoidectomy children whose corresponding value for variable A32 was greater than the mean for the adenoidectomy children in group 3 i.e. $A32 > 91.19\%$ (cf. Table 10 p. 45).

Regression analyses were performed with one of the dentition variables mentioned above as regressand. The regressors were variables for mouth breathing (A15), size of adenoids (A32) and tongue position (A129).

The regression analyses were performed with a stepwise procedure, the variable for size of adenoids (A32) being introduced first, followed by the variable for mouth breathing (A15) and

Table 49 *Regressand A107 Angle between mandibular and nasal lines*

Regression coefficients, their std. error level of significance (marked with asterisks), partial correlation coefficients, the total correlation coefficient (R^2), and the standard deviation of the residuals (R.S.D.), in an analysis of 32 regressors

Regressors	Coefficient	Std. error	t value	Partial corr
Constant	56.9900	10.8710	5.24	—
A70 Preop airflow after nose drops	-0.1377	0.0536	-2.57	-0.20
A85 n-s	-0.4088	0.1163	-3.51	-0.27
A96 Height of upper lip	0.5928	0.1603	3.69	0.28
A97 Height of lower lip	0.4051	0.0989	4.10	0.31
A105 ss-n-sm	0.8107	0.1624	4.99	0.37
A124 ss-n-ba	-0.4575	0.1089	-4.20	-0.31

$R^2 = 0.45$ R.S.D. = 4.19

The relationships obtained between the regressand and regressors A85 Anterior cranial base length A105 Angle ss-n-sm and A124 Angle ss-n-ba, may be regarded as indicators of the same facial morphology. The negative relationship between the angle ss-n-ba (A124) and the angle between the mandibular and nasal lines (A107) agrees with descriptions of individuals with small values for the angles s-n-sa and s-n-sm (Björk, 1947; Lindgård, 1953; Solow, 1966; Hasund & Remme, 1967).

The relationship between preoperative airflow (A70) and the regressand can be interpreted in part as a reflection of the same underlying cause and in part as an expression for a causal connection.

The latter interpretation reflects the view that the determinative value of A70 probably includes influences from variables for mode of breathing and adenoids as well as the consideration that posterior rotation of the lower jaw is facilitated in mouth breathers. It has been pointed out by Ricketts (1968) that such posterior rotation occurs in mouth breathers because they often hold the head tilted slightly backwards.

Summary

This multiple regression analysis shows that a large angle between the mandibular and nasal lines is often found in children with a large angle ss-n-sm, a small angle ss-n-ba, long

	$R^2=0.09$ R.S.D. =2.16.				

then the variable for tongue position (A129). The results of the three stages are shown in Tables 50, 51 and 52.

Since the groups are comparatively small true relationships will be more difficult to demonstrate in these analyses than in those involving all the children.

In the case of the variable for tongue position (A129) none of the analyses demonstrated any significant regression coefficients.

In the case of the dentition variables A46 Angle between upper incisors and nasion-sella line, and A48 Angle between lower incisors and mandibular line, the regression analyses indicate that the relationship between size of adenoids and these dentition variables is established via mouth breathing.

In the case of dentition variable A49 Upper

arch width between first molars, no such indication is detectable in the regression analysis.

No support has been obtained for the hypothesis that the relationship between these dentition variables (A46, A48 and A49) on the one hand and size of adenoids and mouth breathing on the other can be attributed to tongue position.

These observations refer to conditions before adenoidectomy. The question could be tackled better however if these initial observations were combined with conditions one year after adenoidectomy since this operation can be expected to affect size of adenoids, mode of breathing and tongue position and consequently one would expect to find a change in the dentition if the causal mechanism suggested above does in fact exist.

CHAPTER 8

Number of observed and expected significant analyses at the 5%, 1% and 0.1% levels

A total of 17 024 analyses of significance have been performed in this study and of these, 2255 proved to be significant at the 0.1% level, 3427 at the 1% level and 4988 at the 5% level. Assuming all differences to be due to chance, the hypothetical number of expected significant analyses amounts to $0.001 \times 17,024 = 17.0$ at the 0.1% level, $0.01 \times 17,024 = 170.2$ at the 1% level and $0.05 \times 17,024 = 851.0$ at the 5% level.

From this it can be seen that a considerable proportion of the significant results obtained at the 5% level, namely $(0.05 \times 17,024) / 4988 = 17.1\%$ can be suspected of being artefacts. Conclusions concerning differences, correlation coefficients and regression coefficients at the 5% level should therefore be regarded with caution.

At the 1% level, however the number of artefact relationships and differences amounts

Table 53 The hypothetical number of expected significant variables (assuming all differences to be due to chance) at the three levels of significance in relation to the observed number of significant variables

		Level of significance								
		0.1			1			5		
		Observed	Expected	Expected/Observed	Observed	Expected	Expected/Observed	Observed	Expected	Expected/Observed %
Differences between means	Total number of differences obtained									
	1333	142	1.3	0.9	236	13.3	5.6	394	66.6	16.9
Simple correlation analyses	Total number performed									
	15,225	2077	15.2	0.7	3137	152.2	4.9	4326	761.2	16.7
Multiple regression analyses	Total number performed									
	466	31	0.5	1.6	45	4.6	10.2	67	23.0	34.3
Differences, correlation analyses and regression analyses	Total number									
	17,024	2255	17.0	0.8	3427	170.2	4.9	4988	851.0	17.1

to no more than approximately 5% (4.9%) which is a risk one should be prepared to take. At the 0.1% level the corresponding incidence of artefact relationships and differences is rather less than 1% (0.8%) which is to be regarded as fully acceptable.

Summing up it can be noted that the detail

ed discussion of correlation coefficients, regression coefficients and differences is only justified for values at the 1% and 0.1% levels of significance. These findings serve to explain the scarcity of comments in the present study concerning relationships and differences at the 5% level.

Frequency of adenoid facies as assessed from photographs

Results

The numerical and percentage frequencies of so-called adenoid facies (see Fig. 3 p 16) as assessed from photographs by an orthodontist and an otologist are presented in Table 54. Such assessments were made for all the 81 children in the adenoidectomy group and 77 of the controls (no photograph was available for the other 4 controls).

It will be seen from the table that the frequency of so-called adenoid facies is considerably higher among the adenoidectomy children than the controls. The difference is highly significant ($P < 0.001$).

There is good agreement between the two observers' assessments. Judging from the cases which both observers assessed in the same way the frequency of adenoid facies in the present study amounted to 5.9% in the group of children who underwent adenoidectomy. Only one of these children belonged to group 4, i.e.

adenoidectomy as a result of recurrent otitis media.

Adenoid facies was also noted in about 4% of the control children. Only one of these controls belonged to group 3, i.e. the control group for children with large radiographic size of adenoids but no clinical breathing discomfort.

Discussion

Of the children with enlarged adenoids who underwent adenoidectomy only about one in four presented so-called adenoid facies. More over this facial type was registered in some, albeit only a few of the controls. In an unselected study however one would expect to find a larger number of children with so-called adenoid facies than in the present control group, since a number of adenoidectomy cases would be included in an unselected series.

Table 54. Frequency of children with so-called adenoid facies in the adenoidectomy group and the control group as assessed independently by two observers.

The figures in brackets show the number of children who were classified in the same way by both observers.

Observer	Adenoid facies in adenoidectomy group		Adenoid facies in controls	
Orthodontist	28 (21)	34.5 (25.9)	4 (3)	5.0 (3.9)
Otologist	25 (21)	30.9 (25.9)	6 (3)	7.8 (3.9)

General discussion and conclusions

CONCERNING THE EFFECT OF ADENOIDS ON MODE OF BREATHING AND NASAL AIRFLOW AND THEIR RELATIONSHIP TO CHARACTERISTICS OF THE FACIAL SKELETON AND THE DENTITION

Is there a causal connection between adenoids and mouth breathing?

The influence of adenoids on the mode of breathing has been variously assessed in the literature but it seems to be generally agreed that they may be a contributory cause of mouth breathing. It has even been asserted for instance by Brash (1929) Nelvert (1939) Cooke (1940) Leech (1958) Moyers (1963) and Reed (1963) that adenoids are the primary cause of mouth breathing.

In children with adenoids the relationship between their size and the size of the nasopharynx has been cited as a decisive factor for oral or nasal breathing by Siebenmann (1897) Nordlund (1918) Bernfeld (1927) Brash (1929) Schüller (1929) Emalie, Massler & Zwemer (1952) Ricketts (1954) Subtelny (1954) Goldman & Bachman (1958) and Lubarth (1960).

The present study has shown that a relationship exists between size of adenoids and mouth breathing. In the multiple regression analysis with mouth breathing as the dependent variable (see p. 84) the variable for size of adenoids gave a high coefficient of determination ($R^2 = 0.70$) by itself and this was further increased when the variable for size of nasopharynx was also introduced.

That the size of the nasopharyngeal airway is important for the mode of breathing has been demonstrated in Fig. 24 (p. 86) which

shows that mouth breathers comprise 93% (41 out of 44 children) of the group with a small nasopharyngeal passage (zone I) but only 5% (4 out of 76 children) of the group with a large passage (zone II). The diagram also shows that a small nasopharynx combined with small adenoids is only occasionally accompanied by mouth breathing. Similarly even children with large adenoids may have an adequate air passage if the nasopharynx is also large. Such children are consequently not obliged to resort to mouth breathing.

The present results provide no direct indication of the population incidence of mouth breathing as caused by adenoids combined with a small nasopharyngeal airway. Compared with the total population the adenoidectomy group is overrepresented in relation to the controls.

Another finding of interest is that size of adenoids according to the clinical assessment displays almost the same correlation with mouth breathing as size of adenoids measured on lateral cephalometric radiographs.

The relationships obtained warrant the conclusion that adenoids lead to mouth breathing primarily in children with a small nasopharynx. In these children therefore adenoidectomy is especially indicated as a means of promoting a change to nasal breathing.

How is nasal airflow influenced by adenoids?

In order to obtain an objective picture of the passage of air through the nasopharynx recordings were made of nasal airflow in lit/min .

The results show that nasal airflow is low in children with large adenoids and high in those with small or no adenoids (cf. Fig. 25 p. 87) and that the size of nasal airflow is essentially determined by the relationship between size of adenoids and size of nasopharynx.

It is also shown that the nasal airflow increases after adenoidectomy.

Objective recordings of nasal airflow to elucidate its relationship with size of adenoids have earlier been described by Stoksted (1951) and Linder Aronson & Bäckström (1960).

The present results show that size of adenoids is decisive for the rate of nasal airflow only in children with very large adenoids. This implies that the size of the nasopharynx is of little importance for nasal airflow if the adenoids are so large that they severely impede or entirely obstruct the passage of air. The size of the nasopharynx is also of little account for nasal airflow if there are no adenoids because the passage of air is then adequate regardless of the size of the nasopharynx. It is chiefly in children with small or moderate adenoids that the size of the nasopharynx is of essential importance for nasal airflow. The effect of small or moderate adenoids on nasal airflow will accordingly vary with the size of the nasopharynx. Even children with small adenoids may thus have a low nasal airflow if the nasopharynx is also small. Particular attention should therefore be paid to the size of the nasopharynx when assessing the indications for adenoidectomy.

It is remarkable that although the correlations between adenoids and mouth breathing and adenoids and airflow are comparatively strong (0.66, -0.45 respectively), the correlation between mouth breathing and airflow is rather weak (-0.30). From this it must be concluded, like Rasmus & Jacobs (1969) that assessments of mode of breathing cannot be regarded as an acceptable substitute for measurements of nasal airflow and vice versa. This serves to emphasize the diagnostic importance of airflow measurements according to the present method as a means of demonstrating an impaired nose breathing capacity—even in cases where the mode of breathing has been established.

The present study thus provides an objective picture of the impaired function in the nose and the importance of adenoids.

Concerning the secondary effects of nasal obstruction a good deal of research has been conducted on the lower respiratory airways. It has been found by Lüscher (1930) that the stimulus produced by air currents on the trigeminal nerves in the nasal mucous membrane played an important part in the movement of the thorax-lung system by reflex action. Furthermore, like Sencer (1930) and Kreevinsch (1932), he reported disturbance of the acid-base balance in the blood of patients with nasal obstruction and suggested that this might be due to reduced pulmonary ventilation.

This question has attracted renewed attention in recent years as a result of extensive investigations by Ogura et al. (1964, 1966, 1968 a, b), Togawa et al. (1966) and Umo et al. (1968) who have investigated the influence of nasal obstruction on pulmonary mechanics. In successive studies they observed decreased elasticity of the lungs and increased pulmonary (airway and tissue) resistance in 97 subjects with relatively high nasal obstruction. These changes were observed during mouth breathing as well as nasal breathing and were directly related to the degree of nasal obstruction. The authors suggest that the changes in pulmonary function are reversible and probably caused by way of a reflex action.

Chronic upper airway obstruction as a new and previously unrecognized cause of heart failure was first presented by Menasche et al. (1965). Soon thereafter Noonan (1965) described two cases of reversible cor pulmonale due to hypertrophy of tonsils and adenoids. Luke et al. (1966) have reported four patients with severe nasopharyngeal obstruction who presented cardio-respiratory complications ranging from moderate cardiac enlargement and right ventricular hypertrophy to cor pulmonale and pulmonary edema. Improvement following tonsillectomy and adenoidectomy was impressive.

A causal connection between chronic nasopharyngeal obstruction on the one hand and hypovenilation and cor pulmonale on the other has been described in a total of four cases by

Levy et al. (1967) Pillapil et al (1967) and Massumi et al (1969) In all these cases, adenoidectomy or tonsillectomy was followed by substantial improvement.

Even if the number of published cases with severe pulmonary and cardiac changes due to chronic nasopharyngeal obstruction is small in relation to all the children who experience discomfort from adenoids, it is conceivable that the lower respiratory airways are affected to some extent in many young children with nasal obstruction. Considering that the reported changes appear to be reversible early diagnosis is called for and relief of the obstruction. As indicated by the results of the present study the objective registration of nasal airflow is an important diagnostic aid for evaluating nasal respiration. Indirectly the results also provide further evidence of the value of generous indications for adenoidectomy particularly in children with a small nasopharynx.

Is there a connection between adenoids and so-called adenoid facies?

The question whether adenoids are associated with a special facial type known as adenoid facies has been discussed ever since Meyer (1868) drew attention to the deleterious effect of adenoids on the hearing as well as on the general condition of the growing child. It has been asserted on the one hand that adenoids combined with mouth breathing lead to special facial characteristics (e.g. Körner 1891, Cooke 1940, McCoy 1941, Massler, Poncher & Schour 1945, Negus, 1955, Moyers, 1963) and, on the other that this combination has no such effect (e.g. Kingsley 1888, Siebenmann 1897, Whitaker 1911, Nordlund, 1918, Brash 1929, Ballard, 1957 and Tulley 1966).

In the present study photographs of the children were judged independently by two observers and it was found that only about 25% of all the children who underwent adenoidectomy were classified as having so-called adenoid facies. Furthermore adenoid facies was judged to be present in about 4% of the controls. The number of children with so-

called adenoid facies would probably be somewhat higher in an unselected population than in the present control group since a number of adenoidectomy cases would be included in an unselected series. This means that in a screening based on facial type, many cases that call for adenoidectomy would be missed at the same time as some of the cases selected would not be in need of adenoidectomy.

In the comparisons with respect to variables for the facial skeleton, the children who underwent adenoidectomy for obstructed nose breathing differed significantly from the controls. The facial characteristics that distinguished the group of children who underwent adenoidectomy on account of obstructed nose breathing were as follows: large face height, large angles between the mandibular line and the nasal and nasion sella lines, a tendency to small values for the angles s-n-s and s-n-sm, small sagittal depth of nasopharynx, small index values for face width/face height, cranial base depth/face height and face depth/face height, as well as large height of upper and lower lips. The skeleton variable of greatest importance for mouth breathing appears to be size of nasopharynx. As already pointed out, the combination of large adenoids and small nasopharynx is commonly accompanied by mouth breathing. Other skeleton variables appear to be of subordinate interest in this respect. The skeletal type that was found to characterize mouth breathing in this study is distinguished in the first place by skeletal characteristics that are correlated to size of nasopharynx and, in the second place by skeletal characteristics that may give a predisposition for the development of adenoids.

It is also noteworthy that the children who underwent adenoidectomy solely on account of recurrent otitis media did not display the distinguishing characteristics that marked the facial skeleton of those with nasal obstruction on account of adenoids. In this respect, the former group did not differ significantly from the control children.

From this it can be concluded that adenoids

occur in children of various facial types. Obstructed nose breathing on account of adenoids appears to be most common among children with a leptoprosopic type of face and a small nasopharynx.

Is tongue position affected by adenoids?

The question whether children with large adenoids have a different tongue position from those whose airways are free must be related to the question of whether they breathe through the mouth. It has been maintained that the tongue is held low in mouth breathing (Subtelny 1954 Holik, 1957 Ricketts, 1958 a) and it appears natural that this should be so.

A clear relationship between size of adenoids and tongue position was found for the children in the present study. The relationship indicates that children with large adenoids hold the tongue low. The same children also displayed a positive relationship between mouth breathing and a low tongue position.

Is the dentition affected by adenoids?

Whether and, if so, how adenoids are related to a particular type of dentition are questions that have been discussed in the literature ever since Tomes (1872) reported that children who are mouth breathers on account of large adenoids usually display contracted, V-shaped dental arches. It is not, however, the presence of adenoids which is held responsible but the resultant development of mouth breathing. Special types of occlusion combined with adenoids and mouth breathing have been described for instance, by Bloch (1903), Michel (1908) Körbitz (1910), Izard (1925) Kantorowicz (1916) Wustrow (1917), Nelfert (1939), Cooke (1940) McCoy (1941), Massler Poncher & Schour (1945) Subtelny (1954), Negus (1955) Dryzng (1963), Joshi (1964) and Ricketts (1968). The type usually described as a consequence of prolonged mouth breathing is a narrow V-shaped upper jaw with a high palatal vault, proclined upper incisors and a posterior relation between the jaws. In the literature (e.g. Lischer 1912, Strang, 1933 Bowen &

Balyeat, 1934 Nelfert, 1939 McCoy 1941 Ballenger & Ballenger 1943 Subtelny 1954 Moyers, 1963 Howell, 1966) proclination of the upper incisors in mouth breathers is usually attributed to reduced pressure from a short upper lip and a proclining force from the lower lip against the palatal surfaces of the upper incisors.

The opposite opinion—that the type of dentition is not affected by the presence of adenoids combined with mouth breathing—has been maintained, for instance, by Kingsley (1888), McKenzie (1909) Whitaker (1911) Wallace (1927) Brash (1929), Howard (1932) Sillman (1942), Hartsook (1946), Huber & Reynolds (1946), Ballard & Cwynne Evans (1958), Leech (1958) Linder Aronson & Blackström (1960) and Backlund (1963).

In the present study relationships were found between adenoids on the one hand and, on the other, a narrow upper arch, crossbite or a tendency to crossbite, retroclined upper and lower incisors, a short lower arch and large angles between the occlusal line and the mandibular and nasion-sella lines. This type of dentition was also displayed by the mouth-breathing children. Thus the differences between the type of dentition usually attributed to mouth breathers and the results of this study chiefly refer to the inclination of the upper and lower incisors, the height of the palatal vault and the sagittal relationship between the upper and lower arches. It was furthermore found in the present study that a long upper lip was more common among the mouth breathers than among the nose breathers.

The retroclination of the upper incisors in the present mouth breathers can therefore be interpreted as a consequence of an influence of muscles of the upper lip when the mouth is held open. It is conceivable that this involves increased tension in the upper part of the orbicularis oris muscle, resulting in posterior pressure against the incisors because the tendon plates attaching this muscle at the angles of the mouth are held back in turn by the buccinator and triangularis muscles (Petřín 1948). The retroclination of

Levy et al (1967) Pilapil et al. (1967) and Massumi et al (1969) In all these cases, adenoidectomy or tonsillectomy was followed by substantial improvement

Even if the number of published cases with severe pulmonary and cardiac changes due to chronic nasopharyngeal obstruction is small in relation to all the children who experience discomfort from adenoids it is conceivable that the lower respiratory airways are affected to some extent in many young children with nasal obstruction. Considering that the reported changes appear to be reversible early diagnosis is called for and relief of the obstruction. As indicated by the results of the present study the objective registration of nasal airflow is an important diagnostic aid for evaluating nasal respiration. Indirectly the results also provide further evidence of the value of generous indications for adenoidectomy particularly in children with a small nasopharynx.

Is there a connection between adenoids and so-called adenoid facies?

The question whether adenoids are associated with a special facial type known as adenoid facies has been discussed ever since Meyer (1868) drew attention to the deleterious effect of adenoids on the hearing as well as on the general condition of the growing child. It has been asserted on the one hand that adenoids combined with mouth breathing lead to special facial characteristics (e.g. Körner 1891 Cooke 1940 McCoy 1941 Massler Poncher & Schour 1945 Negus, 1955 Moyers, 1963) and, on the other, that this combination has no such effect (e.g. Kingsley 1888 Siebenmann, 1897 Whitaker 1911 Nordlund 1918 Brash 1929 Ballard 1957 and Tulley 1966).

In the present study photographs of the children were judged independently by two observers and it was found that only about 25% of all the children who underwent adenoidectomy were classified as having so-called adenoid facies. Furthermore adenoid facies was judged to be present in about 4% of the controls. The number of children with so-

called adenoid facies would probably be somewhat higher in an unselected population than in the present control group since a number of adenoidectomy cases would be included in an unselected series. This means that in a screening based on facial type, many cases that call for adenoidectomy would be missed at the same time as some of the cases selected would not be in need of adenoidectomy.

In the comparisons with respect to variables for the facial skeleton, the children who underwent adenoidectomy for obstructed nose breathing differed significantly from the controls. The facial characteristics that distinguished the group of children who underwent adenoidectomy on account of obstructed nose breathing were as follows: large face height, large angles between the mandibular line and the nasal and nasion-sella lines, a tendency to small values for the angles s-n-as and s-n-sm, small sagittal depth of nasopharynx, small index values for face width/face height, cranial base depth/face height and face depth/face height, as well as large height of upper and lower lips. The skeletal variable of greatest importance for mouth breathing appears to be size of nasopharynx. As already pointed out, the combination of large adenoids and small nasopharynx is commonly accompanied by mouth breathing. Other skeletal variables appear to be of subordinate interest in this respect. The skeletal type that was found to characterize mouth breathing in this study is distinguished in the first place by skeletal characteristics that are correlated to size of nasopharynx and, in the second place, by skeletal characteristics that may give a predisposition for the development of adenoids.

It is also noteworthy that the children who underwent adenoidectomy solely on account of recurrent otitis media did not display the distinguishing characteristics that marked the facial skeleton of those with nasal obstruction on account of adenoids. In this respect the former group did not differ significantly from the control children.

From this it can be concluded that adenoids

during an intermediary. The hypothesis reproduced in the heading to this section recognizes that the presence of adenoids is associated with mouth breathing and that a low tongue position is more common in children who are mouth breathers than in those who are not.

The analyses in this study have shown that the variable for mouth breathing serves as a link in the relationship between adenoid variables and the dentition variables for the angle between the upper incisors and the nasion-sella line and the angle between the lower incisors and the mandibular line. The variable for tongue position, on the other hand, lacked importance as a link in this relationship. This may possibly support the opinion that mouth breathing affects these angles via lip pressure, when the mouth is held open, rather than via a low tongue position.

Concerning the width of the upper arch between first molars, a significant relationship was only found with size of adenoids. In this connection it should be remembered that nasal obstruction from adenoids is more pronounced

in children with a special facial type, e.g. a long and/or narrow face and a small nasopharynx. It should be emphasized, however that conclusions based on these analyses do not rule out the possibility of other mechanisms in the relationships demonstrated between adenoids combined with mouth breathing and various characteristics of the dentition.

In order to throw further light on the question whether the relationship between adenoids and dentition variables can be explained by adenoids causing mouth breathing and this in turn affecting tongue position and thereby the dentition, studies are required, for instance concerning the development of the dentition after adenoidectomy in mouth breathers, since this operation can be expected to affect size of adenoids, mode of breathing and tongue position.

Since the combustion of adenoids and mouth breathing appears to affect the dentition to some extent, assessments of the indications for adenoidectomy should include an orthodontic evaluation.

upper incisors in mouth breathers can moreover be regarded as a parallel phenomenon to the facial type of these children. Thus it has been reported by Leech (1958) that Angle Cl. II 2 is more common than Cl. II 1 in individuals with large adenoids.

The retroclination of the lower incisors in the present mouth breathers is also interpreted as a result of increased tension in the orbicularis oris muscle when the mouth is held open, the mechanism corresponding to that outlined above for the upper incisors with the zygomaticus major and caninus muscles acting instead of triangularis. A low tongue position in mouth breathing (Subtelny 1954, Holik 1957, Ricketts 1958 *a*) with the tongue possibly held withdrawn as well may have been a contributory cause (Hovell 1962). This retroclination probably also represents a parallel phenomenon to the facial type of these mouth breathers. In this context it should be noted that, in relation to the nasal and nasion-sella lines, the mandibular line lay approximately 5° more backwards-upwards in the mouth breathers compared with the controls which should give the former a smaller angle between the lower incisors and the mandibular line.

The relationship between a high palatal vault and adenoids combined with mouth breathing that has been described for instance, by Kärbitz (1910), Kantorowicz (1916), Wustrow (1917), Izard (1925), Cooke (1940) and Massler Poncher & Schour (1945) could not be demonstrated in the present children.

In the analysis in this study of the relationship between an index for height of palatal vault and width of upper arch between first molars on the one hand and, on the other, adenoids and mouth breathing it was found that a narrow upper arch and/or a high palatal vault occurs more frequently in mouth breathers than in nose breathers. Mouth breathing in the former individuals is to be regarded as a consequence rather than a cause of a narrow upper arch and/or a high palatal vault. In this context, the relationship between arch width and mouth breathing is considered to be

stronger than that between height of palatal vault and mouth breathing. A similar opinion has been expressed by Subtelny (1954) namely that the impression of a high palatal vault in mouth breathers can be explained as an optical illusion due to a narrow upper arch.

The relationship reported between adenoids combined with mouth breathing and a postnormal occlusion, e.g. by Angle (1907), McCoy (1941), Hemley (1944), Massler Poncher & Schour (1945), Graber (1961) and Joshi (1964) could not be verified in the present study.

In keeping with previous reports that children with adenoids combined with mouth breathing often have a narrow upper arch (e.g. Tomes, 1872; Cooke, 1940; McCoy 1941; Massler Poncher & Schour 1945; Subtelny 1954; Negus, 1955; Druyting, 1963; Moyers, 1963; Ricketts, 1968) the present children who underwent adenoidectomy for obstructed nose breathing were found to have a narrow upper arch more frequently than the nose breathers. A small upper arch in these adenoidectomy children could be explained as a parallel phenomenon to their long, narrow type of face with a small nasopharynx and narrow nose. This, however, does not rule out the possibility of a certain causal relationship between upper arch width and adenoids, with mouth breathing and a low tongue position as a result. This question can best be elucidated by follow up studies after adenoidectomy.

The relationships obtained in this study between adenoid and dentition variables confirm the assumption that a relationship exists between the presence of adenoids and special characteristics of the dentition.

Can the relationship between the presence of adenoids and dentition variables be attributed to adenoids resulting in mouth breathing which in turn affects tongue position and thereby the dentition?

The relationships described between the presence of adenoids and dentition are difficult to explain in direct causal terms without intro-

during an intermediary. The hypothesis reproduced in the heading to this section recognizes that the presence of adenoids is associated with mouth breathing and that a low tongue position is more common in children who are mouth breathers than in those who are not.

The analyses in this study have shown that the variable for mouth breathing serves as a link in the relationship between adenoid variables and the dentition variables for the angle between the upper incisors and the nasion-sella line and the angle between the lower incisors and the mandibular line. The variable for tongue position, on the other hand lacked importance as a link in this relationship. This may possibly support the opinion that mouth breathing affects these angles via lip pressure, when the mouth is held open, rather than via a low tongue position.

Concerning the width of the upper arch between first molars, a significant relationship was only found with size of adenoids. In this connection it should be remembered that nasal obstruction from adenoids is more pronounced

in children with a special facial type, e.g. a long and/or narrow face and a small nasopharynx. It should be emphasized, however that conclusions based on these analyses do not rule out the possibility of other mechanisms in the relationships demonstrated between adenoids combined with mouth breathing and various characteristics of the dentition.

In order to throw further light on the question whether the relationship between adenoids and dentition variables can be explained by adenoids causing mouth breathing and this in turn affecting tongue position and thereby the dentition, studies are required, for instance concerning the development of the dentition after adenoidectomy in mouth breathers, since this operation can be expected to affect size of adenoids mode of breathing and tongue position.

Since the combination of adenoids and mouth breathing appears to affect the dentition to some extent, assessments of the indications for adenoidectomy should include an orthodontic evaluation.

General summary

Chapter 1 reviews the literature concerning adenoids in relation to mode of breathing as well as to special facial types and dentition characteristics

Chapter 2 presents the purpose of the present study namely:

(a) to study which relationships exist between adenoids and variables representing mode of breathing, airflow and type of dentition

(b) to study how mode of breathing, airflow and type of dentition are related to certain variables for the facial skeleton,

(c) to try to establish whether there is a relationship between adenoids and the occurrence of so-called adenoid facies, and

(d) to try to establish whether a modified tongue position in the presence of adenoids represents an etiological factor for malocclusion

Chapter 3 describes the material and methods

The present investigation was conducted on 162 children from the county of Örebro in Central Sweden born in the years 1955–61

The patients (81) comprise children selected for adenoidectomy by otologists. The controls (81) were chosen on the basis of the adenoidectomy children's age, sex and number using the National Register

The same studies were made on adenoidectomy children and controls. The material is separated into 5 different groups. The controls are divided between groups 1–3 depending on the size of adenoids as studied on lateral cephalometric radiographs: group 1 no adenoids, group 2 small or moderate adenoids, group 3 large adenoids

Group 4 comprises the children who underwent adenoidectomy on account of recurrent

otitis media only and group 5 those who underwent the operation for obstructed nose breathing, with or without otitis media.

All the subjects have been studied with respect to 173 variables, grouped as anamnesis, adenoid, dentition, airflow, skeleton-lip and tongue variables. Data on each subject include direct facial measurements, a photograph of the face, measurements on lateral and frontal radiographs, measurements on casts and recordings of nasal airflow at differential pressures of 10, 15 and 20 mm H₂O

The method for measuring nasal airflow consists of simultaneous recordings of the rate of airflow and the pressure gradient between the nasopharynx and the nostrils. The recordings were made before and 15 min after the administration of nose drops on two occasions one month apart. Adenoidectomy was performed on all the subjects in groups 4 and 5 between these two occasions

Chapter 4 presents the errors of method for all the variables

Chapter 5 describes the statistical methods used for the analysis of relationships, namely simple correlation analysis and multiple regression analysis.

All calculations in this study have been performed on the UDAC (Uppsala computer CDC 3600)

Chapter 6 describes the results of comparisons of means between the control and adenoidectomy groups as well as the results of the simple correlation analyses. For the children in this study these results show that

the division of the material into groups 1–5 is fully justified. In this context it is particularly noteworthy that the children who underwent adenoidectomy for obstructed nose breath-

ing (group 5) differ significantly in several respects not only from the controls in groups 1 and 2 but also from the children who underwent adenoidectomy on account of otitis media (group 4)

the controls include 11 children (group 3) with no clinical discomfort in spite of having large adenoids

adenoids lead to mouth breathing;

size of adenoids decreases with increasing age

good agreement was found between clinical assessments of size of adenoids and measurements on radiographs,

the children who underwent adenoidectomy for obstructed nose breathing had larger adenoids in relation to the nasopharynx than those who underwent the operation on account of recurrent otitis media

nasal airflow measured at a differential pressure of 10 mm H₂O is lower for large than for small adenoids and increases after adenoidectomy

there is a relationship between the presence of adenoids and particular characteristics of the dentition. Compared with children who have no adenoids, those with adenoids and obstructed nose breathing more frequently present a narrow upper arch, crossbite or a tendency to crossbite, retroclination of upper and lower incisors in relation to the base lines, a short lower arch and large angles between the occlusal line and the mandibular and nasion-sella lines

adenoids with obstructed nose breathing as a result is commonly associated with a particular type of facial skeleton. Compared with children who have no adenoids, those who underwent adenoidectomy for obstructed nose breathing more commonly present a large face height, large height of upper and lower lip, a tendency to small values for the angles s-n-as and s-n-sm, large angles between the mandibular line and the nasion-sella and nasal lines and small index values for face width/face height, cranial base depth/face height and face

Fig. 39 Tracings of lateral cephalometric radiographs showing significant differences between the children who underwent adenoidectomy for obstructed nose breathing (group 5) and the controls (group 1) with respect to variables representing adenoids, the dentition, the skeleton, lips and position of the tongue

children with adenoids and obstructed nose breathing more often hold the tongue low than those without adenoids.

A composite picture of the differences between groups 1 and 5 is given in Fig. 39. Chapter 7 describes the results of the multiple regression analyses. For the children in this study these results show that:

mouth breathing can largely be explained as a consequence of size of adenoids and size of the bony nasopharynx

nasal airflow measured at a differential pressure of 10 mm H₂O is determined in the first place by size of adenoids and sagittal depth of the bony nasopharynx. Furthermore, the size of the nasopharynx is of little importance for airflow when the adenoids are very large and block the passage of air. The size of the nasopharynx is also of little importance for airflow in the absence of adenoids, since the

Acknowledgements

I wish to express my sincere thanks to all those who, in a variety of ways, have helped me to fulfil this work.

To my former chief Professor Anders Lundström, Odont.D. Dean of the School of Dentistry at Karolinska Institutet, for instigating, personally supporting and critically evaluating this investigation throughout its length. His inspiration has been essential for the conception and execution of this study.

To Professor Gunnar Aschan, M.D. Head of the Department of Otorhinolaryngology Regionsjukhuset, Linköping, for invaluable and never-failing support and stimulation during the investigation. I am specially grateful to him for introducing me to the field of rhinomanometry.

To Ass. Professor Gunnar Eklund, Ph.D. Department of Statistics, University of Stockholm, for his interest and intimate collaboration as regards the statistical problems of this work and for help with data processing as well as for invaluable advice in many other respects.

To Ass. Professor Jan-Erik Laage Hellman, M.D. Head of the Department of Otorhinolaryngology Regionsjukhuset, Örebro and Ass. Professor Stig Sandmark, M.D. Department of Otorhinolaryngology Regionsjukhuset, Örebro, for generous assistance in the collection of the material and for valuable advice.

To Professor Arne Forsberg, M.D. Head of the Department of Roentgenology School of Dentistry Karolinska Institutet, for valuable help with roentgenologic problems and for critical reading of manuscripts.

To Ass. Professor Rolf Jensen, Odont.D. Department of Orthodontics, School of Den-

istry Karolinska Institutet, for valuable help with cinematography.

To Dr John Hedlin, Head of the Public Dental Service, Örebro län landsting, for kindness in providing research facilities.

To Ass. Professor Allan Helligren, Acting Head of the Department of Orthodontics, School of Dentistry Karolinska Institutet, for critical reading of manuscripts.

To Mr Anders Haglund, Uppsala datacentral, for valuable assistance with data processing.

To Mr Henry Johansson, Uppsala, and Mr Sven Landin, Örebro for valuable technical assistance.

To Mrs Getrude Voulettae and Mrs Agneta Steen for their invaluable contributions in the production of the illustrations.

To Miss Margot Johansson and Mrs Marie Louise Cristophe for their skilful assistance with secretarial work.

To Miss Margit Sjöstedt, head nurse as well as to the other staff at the Department of Orthodontics at Örebro.

To Mr Patrick Hort, who translated the manuscript.

And lastly I cannot sufficiently thank my wife Margareta, for her great patience and support throughout the investigation.

The investigation was supported by grants from the Odontological Faculty at Karolinska Institutet, Stockholm, Örebro län landsting and the Swedish Dental Society. A Doctorate scholarship has been awarded by the School of Dentistry Stockholm.

Örebro, October 1969

Sten Linder Aronson

passage of air is then sufficient regardless of the size of the nasopharynx. It is chiefly in children with small or moderate adenoids that the sagittal dimension of the nasopharynx is of essential importance for the magnitude of the nasal airflow.

the upper incisors were retroclined in relation to the nasion-sella line in many of the children in adenoidectomy group 5 as well as in children with a large overbite, a small lower face height or a small value for the angle $s-n-s$.

the lower incisors were often retroclined in relation to the mandibular line in children who breathe through the mouth, have a large angle between the mandibular and nasal lines or a small overjet.

a narrow upper arch between first molars is often found in children with a small nasopharynx, short crowded upper jaw or a large angle between the nasal and mandibular lines.

large overjet is often found in children with a large value for the angle $s-s-n-s$, a long upper arch, a large sagittal dimension on the roof of the nasal cavity or a postnormal relation between the upper and lower first molars.

a small overbite is often found in children with crossbite or a tendency to crossbite or a small index value for anterior upper and total face height.

the size of the index for height of palatal vault and upper arch width between first molars is primarily dependent on the age of the child. A narrow upper arch and/or a high palatal vault was frequently found in the children who were mouth breathers.

a large angle between the mandibular and nasal lines is frequently found among children with large values for the angle $s-s-n-s$, small values for the angle $s-s-n-ba$, long upper and lower lips or a short anterior cranial base length.

the relationship between size of adenoids and mouth breathing on the one hand and, on the other, dentition variables such as the angle

between the upper incisors and the nasion-sella line, the angle between the lower incisors and the mandibular line and the width of the upper arch between first molars, could not be explained by tongue position.

Chapter 8 describes the number of observed and expected significant analyses at the 5%, 1% and 0.1% levels.

Chapter 9 is concerned with the frequency of so-called adenoid facies. Assessments of this frequency from photographs show that it is significantly higher for the adenoidectomy children than for the controls. In the present study it was found that so-called adenoid facies was presented by approximately 25% of the children who underwent adenoidectomy on account of recurrent otitis media or obstructed nose breathing. Adenoid facies was also noted in approximately 4% of the children in the control groups.

The results obtained in this study appear to support the present hypothesis that adenoids affect the mode of breathing, which then influences the individual's dentition.

This, of course, does not rule out the possibility that other more complex causal relationships are also involved. The correlation between a narrow nasopharynx and mouth breathing indicates that a particular structure of the facial skeleton influences the development of mouth breathing. It is also conceivable that the structure of the facial skeleton directly influences the development or the size of adenoids. Any such structure that predisposes for adenoids may in itself involve associations to certain characteristics of the dentition that have been found to be connected with mouth breathing. Further elucidation of various conceivable causal mechanisms calls for studies of the development of the dentition after adenoidectomy in mouth breathers. As mentioned on p. 16 such an investigation is being conducted and will be published separately.

$$\frac{r}{\sqrt{1-r^2}} \sqrt{n-2}$$

which—if the true correlation was zero—was considered to be distributed like Student's t with $n-2$ degrees of freedom.

Significance levels

The term "significant" is used in accordance with the following convention. If an observed difference between two means is of such magnitude that the probability P of obtaining a difference at least as great as the observed value is greater than 0.05 (where the null-hypothesis is assumed to hold), then that observed difference is said to be non-significant.

If $0.01 < P < 0.05$, the difference is said to be almost significant and is marked

If $0.001 < P < 0.01$ the difference is said to be significant and is marked

If $P < 0.001$ the difference is said to be (highly) significant and is marked

Multiple regression analysis used in the present study

For a series of n children we wish to study the relation between a dependent variable, y called the regressand, and a set of explanatory variables, $x^{(1)} \dots x^{(k)}$ called regressors. The regressands are variables indicating mode of breathing, air flow and bite characteristics, etc. The k regressors $x^{(1)} \dots x^{(k)}$ may be age, sex, size of adenoids, etc.

In order to study the relation between the y and x variables, a type of equation must first be laid down. Individual numerical values must also be available for each variable. In the present

work equations of the following form have been studied

$$y = b_0 + b_1 x^{(1)} + b_2 x^{(2)} + \dots + b_k x^{(k)}$$

where $b_0, b_1, b_2, \dots, b_k$ are the coefficients which are to be estimated. In estimating these coefficients the principle of least squares has been applied. This principle means that we seek values of coefficients which are constituted in such a way as to yield the smallest possible sum from the following expression

$$\sum (y - b_0 - b_1 x^{(1)} - b_2 x^{(2)} - \dots - b_k x^{(k)})^2$$

If this expression is treated in a purely mathematical fashion, as a maximum-minimum problem we obtain a general solution with the aid of the following $k+1$ linear equations in the $k+1$ unknown coefficients

$$\begin{cases} \sum y = b_0 n + b_1 \sum x^{(1)} + b_2 \sum x^{(2)} + \dots + b_k \sum x^{(k)} \\ \sum y x^{(1)} = b_0 \sum x^{(1)} + b_1 \sum x^{(1)} x^{(1)} + b_2 \sum x^{(1)} x^{(2)} + \dots + b_k \sum x^{(1)} x^{(k)} \\ \sum y x^{(2)} = b_0 \sum x^{(2)} + b_1 \sum x^{(1)} x^{(2)} + b_2 \sum x^{(2)} x^{(2)} + \dots + b_k \sum x^{(2)} x^{(k)} \\ \vdots \\ \sum y x^{(k)} = b_0 \sum x^{(k)} + b_1 \sum x^{(1)} x^{(k)} + b_2 \sum x^{(2)} x^{(k)} + \dots + b_k \sum x^{(k)} x^{(k)} \end{cases}$$

Here $\sum y$ stands for the sum of all individual y values and $\sum y x^{(k)}$ the sum of all individual products of $y x^{(k)}$ etc.

The principle of least squares has been described in detail by Cramér (1945) and Hald (1948), who also explain the method of calculating S.E. for the coefficients.

Predicted value

The y value for an individual (i), predicted with the aid of the regression equation, is defined as

$$\hat{y} = b_0 + b_1 x^{(1)} + b_2 x^{(2)} + \dots + b_k x^{(k)}$$

All statistical analyses were performed in collaboration with Associate Professor G. Eklund, Ph.D. at the Department of Statistics, University of Stockholm.

STATISTICAL METHODS

Notation

Number of cases N or n the latter in the event of missing values.

$$\text{Mean } M = \bar{X} = \frac{\sum X_i}{n} \text{ or } \frac{\sum X_i}{N}$$

where X_i denotes the value for the i th case.

Standard deviation

$$S.D. = \sqrt{\frac{\sum (X_i - M)^2}{n-1}}$$

Standard error of the mean

$$S.E. = \frac{S.D.}{\sqrt{n}}$$

Standard error of the difference between two means, \bar{x} and \bar{y}

$$S.E. = \sqrt{S.E._x^2 + S.E._y^2}$$

Regression analysis

Correlation analysis The correlation coefficient, r of x and y is defined by the expression

$$r = \frac{\sum (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum (x_i - \bar{x})^2 \sum (y_i - \bar{y})^2}}$$

where \bar{x} and \bar{y} denote the means for the x and y series respectively

The partial correlation coefficient between x and y with z held constant.

$$r_{xy.z} = \frac{r(xy) - r(xz) r(yz)}{\sqrt{(1 - r^2(xz))(1 - r^2(yz))}}$$

The residual value for an individual (i) is defined as the observed y value minus the predicted y value.

The residual variance is defined as

$$\frac{\sum \text{residuals}^2}{n-k-1} = \frac{\sum (y - b_0 - b_1 x^{(1)} - b_2 x^{(2)} - \dots - b_k x^{(k)})^2}{n-k-1}$$

where b_0, b_1, \dots, b_k denote the estimated coefficient values.

The standard deviation of the residuals (R.S.D.) is defined as the square root of the residual variance

The coefficient of determination, R^2 i.e. the square of the multiple correlation coefficient, is

$$R^2 = 1 - \frac{(n-k-1) \text{ residual variance}}{\sum (y_i - \bar{y})^2}$$

The residual variance is that part of the variance which remains after the effect of the regressors (independent variables) is removed. It measures the variability due to unexplained causes and irregular measurement error

R^2 serves as a measure of the part of the regressand's variance that is due to the regressors. If the regressors are direct or indirect causal factors of the regressand, the value of R^2 can be said to express their explanative value.

Significance tests

1 In testing the difference between two percentages the χ^2 test with one degree of freedom was used. Yates' correction was applied

2 In testing differences between means, the following approximately t -distributed ratio was formed

$$t = \frac{\bar{x} - \bar{y}}{S.E.}$$

3 In testing whether the regression coefficients differed from 0 the method described by Cramér (1945) and Hald (1948) was used

A t value was produced from the expression $b_j / S.E._{b_j}$

4 In testing whether a correlation coefficient differed from 0 the following ratio was produced

$$\frac{r}{\sqrt{1-r^2}} \sqrt{n-2}$$

which—if the true correlation was zero—was considered to be distributed like Student's t with $n-2$ degrees of freedom.

Significance levels

The term "significant" is used in accordance with the following convention. If an observed difference between two means is of such magnitude that the probability P of obtaining a difference at least as great as the observed value is greater than 0.05 (where the null-hypothesis is assumed to hold), then that observed difference is said to be non-significant.

If $0.01 < P < 0.05$, the difference is said to be almost significant and is marked

If $0.001 < P < 0.01$ the difference is said to be significant and is marked

If $P < 0.001$ the difference is said to be (highly) significant and is marked

Multiple regression analysis used in the present study

For a series of n children we wish to study the relation between a dependent variable, y , called the regressand, and a set of explanatory variables, $x^{(1)}, \dots, x^{(k)}$, called regressors. The regressands are variables indicating mode of breathing, air-flow and bite characteristics, etc. The k regressors $x^{(1)}, x^{(2)}, \dots, x^{(k)}$ may be age, sex, size of adenoids, etc.

In order to study the relation between the y and x variables, a type of equation must first be laid down. Individual numerical values must also be available for each variable. In the present

work equations of the following form have been studied

$$y = b_0 + b_1 x^{(1)} + b_2 x^{(2)} + \dots + b_k x^{(k)}$$

where $b_0, b_1, b_2, \dots, b_k$ are the coefficients which are to be estimated. In estimating these coefficients the principle of least squares has been applied. This principle means that we seek values of coefficients which are constituted in such a way as to yield the smallest possible sum from the following expression

$$\sum (y - b_0 - b_1 x^{(1)} - b_2 x^{(2)} - \dots - b_k x^{(k)})^2$$

If this expression is treated in a purely mathematical fashion, as a maximum-minimum problem we obtain a general solution with the aid of the following $k+1$ linear equations in the $k+1$ unknown coefficients

$$\begin{cases} \sum y = b_0 n + b_1 \sum x^{(1)} + \dots + b_k \sum x^{(k)} \\ \sum y x^{(1)} = b_0 \sum x^{(1)} + b_1 \sum x^{(1)} x^{(1)} + \dots + b_k \sum x^{(1)} x^{(k)} \\ \sum y x^{(2)} = b_0 \sum x^{(2)} + b_1 \sum x^{(1)} x^{(2)} + \dots + b_k \sum x^{(2)} x^{(k)} \\ \sum y x^{(k)} = b_0 \sum x^{(k)} + b_1 \sum x^{(1)} x^{(k)} + \dots + b_k \sum x^{(k)} x^{(k)} \end{cases}$$

Here $\sum y$ stands for the sum of all individual y values and $\sum y x^{(k)}$ the sum of all individual products of $y x^{(k)}$ etc.

The principle of least squares has been described in detail by Cramér (1945) and Hald (1948) who also explain the method of calculating S.E. for the coefficients.

Predicted value

The y value for an individual (i), predicted with the aid of the regression equation, is defined as

$$b_0 + b_1 x^{(1)} + b_2 x^{(2)} + \dots + b_k x^{(k)}$$

All statistical analyses were performed in collaboration with Associate Professor G. Eklund, Ph.D. at the Department of Statistics, University of Stockholm.

STATISTICAL METHODS

Notation

Number of cases N or n the latter in the event of missing values.

$$\text{Mean } M = \bar{x} = \frac{\sum x_i}{n} \text{ or } \frac{\sum x_i}{N}$$

where x_i denotes the value for the i th case

Standard deviation

$$SD = \sqrt{\frac{\sum (x_i - M)^2}{n-1}}$$

Standard error of the mean

$$SE = \frac{SD}{\sqrt{n}}$$

Standard error of the difference between two means, \bar{x} and \bar{y}

$$SE = \sqrt{SE_{\bar{x}}^2 + SE_{\bar{y}}^2}$$

Regression analysis

Correlation analysis. The correlation coefficient, r of x and y is defined by the expression

$$r = \frac{\sum (x - \bar{x})(y - \bar{y})}{\sqrt{\sum (x - \bar{x})^2 \sum (y - \bar{y})^2}}$$

where \bar{x} and \bar{y} denote the means for the x and y series respectively

The partial correlation coefficient between x and y with z held constant

$$r(x-y) = \frac{r(xy) - r(xz)r(yz)}{(1 - r^2(xz))(1 - r^2(yz))}$$

The residual value for an individual (i) is defined as the observed x value minus the predicted y value.

The residual variance is defined as

$$\frac{\sum \text{residuals}^2}{n-k-1} = \frac{\sum (y - b_0 - b_1 x - b_2 x^2 - b_3 x^3 - b_4 x^4)^2}{n-k-1}$$

where b_0, b_1, \dots, b_k denote the estimated coefficient values.

The standard deviation of the residuals (RSD) is defined as the square root of the residual variance.

The coefficient of determination R^2 i.e. the square of the multiple correlation coefficient, is

$$R^2 = 1 - \frac{(n-k-1) \text{ residual variance}}{\sum (y_i - \bar{y})^2}$$

The residual variance is that part of the variance which remains after the effect of the regressors (independent variables) is removed. It measures the variability due to unexplained causes and irregular measurement error.

R^2 serves as a measure of the part of the regressand's variance that is due to the regressors. If the regressors are direct or indirect causal factors of the regressand the value of R^2 can be said to express their explanative value.

Significance tests

1 In testing the difference between two percentages the χ^2 test with one degree of freedom was used Yates correction was applied

2 In testing differences between means, the following approximately t -distributed ratio was formed

$$t = \frac{\bar{x} - \bar{y}}{SE}$$

3 In testing whether the regression coefficients differed from 0 the method described by Cramér (1945) and Hald (1948) was used

A t value was produced from the expression $b_j / S E_{b_j}$

4 In testing whether a correlation coefficient differed from 0, the following ratio was produced

AETIOLOGY

The development of surgery for otosclerosis has produced considerable knowledge of the pathology of the middle ear and, in the process, provided information on other conductive hearing defects which occur with an intact membrane, but which are not of otosclerotic nature. Sooy (1960) reported that, in more than 1100 tympanotomies performed in cases of suspected otosclerosis, 4.2 per cent of the hearing defects were shown to have non-otosclerotic causes. Among these causes it was found that defects in the auditory ossicles (i.e. loss of continuity for any reason) formed an important group.

An exposition of the aetiological factors involved in defects of the auditory ossicles occurring while the tympanic membrane remains intact will be found in the following:

I. Traumatic Fractures and Dislocations of the Auditory Ossicles

A. *Fractures and luxations of the auditory ossicles due to cranial trauma.*

Such conductive interruptions have frequently been described in the literature in recent years. This is most probably due to three factors:

- 1 An increasing number of cranial traumas resulting from the explosive development of modern traffic and industry

- An increased survival rate among this type of patients due to more effective therapy during the acute phase permits diagnosis, during a following quiet phase, of traumatically caused hearing defects, and likewise permits surgical intervention in cases of defects in the transmission system of the middle ear

- 3 The intensive development of otological surgery which has led to an increased prob-

ability of success with reconstructive treatment of the transmission mechanism of the middle ear

Most of these cases will involve patients with longitudinal fractures of the petrous part, as transverse fractures through the petrous part will, as a rule, involve the labyrinth, and thus result in loss of the labyrinthial function. In cases of longitudinal fractures, the labyrinthial function will most often be retained, even though a high-frequency perceptive hearing loss of greater or lesser magnitude will be observed, occasionally with a simultaneous conductive hearing loss (Eascher 1964)

A typical longitudinal fracture of the petrous part will often result in damage to the middle ear at one point or another. As a rule, the fracture line runs from the squamous portion of the temporal bone through the external meatus, tympanic groove, tegmen tympani, passes by the labyrinth and terminates at one of the openings in the base of the skull. The preferred course of the fracture follows the roof, the transition between the roof and the posterior wall, and the posterior wall (Kley 1966). The courses of the fractures, together with displacement of bone fragments and the magnitude of the forces at the instant of the trauma, determine the type and extent of the injury to the auditory ossicles.

Most frequently the fracture follows the upper posterior edge of margo tympanicus, and thus passes very near the incus. As the incus is, in addition, the least stably fixed of the three bones (the other two are stabilized by the tensor tympani muscle and the stapedius muscle in addition to ligaments and, in case of the malleus, by the tympanic membrane as well)

INTRODUCTION

The introduction of tympanoplastic surgery by Wullstein and Zöllner has caused considerable activity toward improvement of the results of such treatment.

These efforts have primarily been concentrated on the development of the most suitable myringoplastic procedures. However, during the past few years, there has been a growing interest in reconstructive surgery on the auditory ossicles.

The object of the present work is—partly on the basis of studies of the literature, and partly on the basis of original clinical and previously published experimental studies—to illustrate the aetiological, diagnostic, and reconstructive problems arising in connection with defects of the auditory ossicles when the tympanic membrane is intact, so that it may be come possible to improve the results of reconstructive surgery on the ossicular chain.

an explosion, boxing the ears, or the like, may also lead to dislocation of the incus (Escher 1964).

II. Defects in the Auditory Ossicles Resulting from Disease

Necrosis of the lenticular process and the distal end of the long process of the incus are occasionally revealed by tympanotomy in patients who are able to recall the incidence of otitis media at an earlier date. Numerous authors have reported such cases (Hamberger and Lidén, 1958 Günzel, 1958 Hough, 1959 Sooy 1960 Andersen et al., 1962). The bony structure will often be found to have been replaced by a fibrous cord which permits the transmission of sound only to a very limited degree. On occasion it will be seen that only the distal end of the long process of the incus has been replaced by fibrous tissue, while the lenticular process remains intact and connected to the head of the stapes by the joint capsule. The long process of the incus thus seems to be more vulnerable to the influences of inflammation than do the remaining parts of the ossicular system, but on rare occasions coincident necrosis of the stapes crura is also revealed.

Otitis of the ossicles, and the pressure of granulation tissue during the suppurative stage, can result in defects in the long process of the incus and the stapes crura.

It seems likely that a capillary insufficiency may well be a contributory cause of such post-inflammatory necroses. A significant portion of the blood supply to the distal parts of the long process and the lenticular process is provided by passages in the mucous membrane covering the bone (Alberti, 1963). If this capillary network is damaged as the result of inflammation in the middle ear conditions suitable for osteonecrosis might well be present. It is well known that necrosis of the long process of the incus and the lenticular process can be seen after stapes operations (Alberti and Dawes, 1961 Smith, 1966 Webb et al., 1966). This is true for both stapes mobilization and stapedectomy. The cause of the necrosis in these cases is

given as the traumatization of the mucous membrane—including the capillaries—both locally at the lenticular process and the long process of the incus as well as the stapes tendon.

III. Auditory Ossicular Defects Resulting from a Cholesteatoma

Cholesteatoma is not infrequently found where there is no anamnesis of otitis media and the tympanic membrane is intact (Riedl, 1957 Everberg, 1965).

A cholesteatoma obviously may injure the ossicles or disrupt their functional continuity

IV. Radiation-Induced Defects of the Auditory Ossicles

Necrosis of the long process of the incus may be found after radiation treatment of malignant tumours in the region of the middle ear. Gyorky and Pollock (1960) have described a case of necrosis of the long process after radiation therapy for an ependymo-blastoma in the bottom of the fourth ventricle. It is suggested that a reduced or interrupted capillary supply in the bone, caused by the radiation, may have contributed to the necrosis. Radiation treatment of malignant tumours in the rhino-pharynx may also result in necrosis of the long process (Andersen et al., 1962).

V. Congenital Defects of the Auditory Ossicles

Any disruption of the development of the first two branchial arches can result not only in facial deformities such as Franceschetti's Syndrome, but in deformities of the ear of greater or lesser severity as well (Altmann, 1955 Edwards, 1964 Mündnich, 1965). The interesting point in this connection is that there are cases where the deformities are primarily localized in the ossicles, while the inner ear develops normally. De Witt (1958) has given this condition the designation *atresia auris minima*.

According to Ombredanne (1959) these cases can be separated into three groups.

the incus will be the bone most likely to suffer dislocation. Therefore, it should not be surprising that incus luxations have been described by many authors (Thorburn, 1957 Gisselson 1958 Bauer 1958 Flisberg and Floberg, 1960 Andersen et al 1962 Ballantyne 1962 Anklesaria 1963 Hammond, 1964 Escher 1964 Does and Bottema 1965). A luxation of the incus can vary from a very slight displacement of the lenticular process of the head of the stapes, with only partial laceration of the joint capsule to complete loosening of the incus and its displacement to for example the external meatus, the mouth of the Eustachian tube or the antrum. It is also possible that a dislocation on the incus may occur in connection with a fracture of one or both of the stapes crura, as there is a significant variation in the massiveness and thus, also in the strength of the crura.

If the fracture should go through the tympanic groove in close proximity to the head of the malleus, there may occur a luxation of the malleus, either alone or with the incus (Hammond, 1964 Kley 1966).

In the case of a horizontal fracture through the mastoid process, involving the posterior edge of the margo tympanicus, Kley (1966) reports that a fracture of the handle of the malleus or the long process of the incus is possible.

Isolated stapes fractures have been described by several authors (Williams, 1958 Robinson, 1961 Retjens 1963 Sadé 1964 Andersen and Elbrønd, 1968). It may be postulated that such fractures have occurred as the result of a temporary dislocation or subluxation of the incus (Kley 1966). A powerful coincident contraction of the stapedius muscle (caused by the trauma) can also be suggested as contributory to the dislocation (Hough, 1959).

Finally it should be mentioned that longitudinal fractures in the petrous part are often accompanied by bleeding from the ear and, not infrequently by leakage of cerebro-spinal fluid as well. In severe cases, brain tissue may also be found in the tympanic cavity and in

the Eustachian tube. A facial paralysis will be found in approximately 15 per cent of these cases.

B Operatively-caused Dislocations of the Incus

A mastoidectomy or antrotomy is not infrequently complicated by a dislocation of the incus when the cells around the entrance to the antrum must be drained (Plester 1957 Schuknecht and Trupiano 1957 Ruskat 1960 Andersen et al 1962 Escher 1964). This type of luxation is naturally more prone to occur when these cells are emptied without the use of a surgical microscope. This luxation consists in the loosening of the ligaments which connect the short process of the incus to the wall of the fossa incudis.

It is well known that mastoidectomy was previously performed very frequently but the use of antibiotics in the treatment of otitis media has resulted in a significant decrease in the number of these operations. A luxation due to surgical treatment will thus occur very seldom.

C. Transmeatal Lesions of the Ossicular System

Puncture injuries, caused by a knitting-needle straw twig etc. inserted through the external meatus, occasionally result in injuries to the auditory ossicles. Escher (1964) describes a case of stapes fracture after a knitting-needle puncture. Incautious therapeutic manipulations can also lead to disruption of the continuity of the ossicles. Escher (1964) mentions a luxation of the malleus caused by the end of an ear syringe. Unfortunate cases of simple tympanic puncture resulting in a luxation of the incudo-stapedial articulation or fracture of the stapes, are also recorded. In all of the above-mentioned cases, a lesion in the tympanic membrane will naturally occur at the time of the injury but as a rule this will heal and not infrequently this healing will proceed without leaving a trace of the puncture. Shock wave traumata through the meatus, caused by

DIAGNOSIS

Defects in the auditory ossicles, and a number of other diseases of the middle ear where the tympanic membrane remains intact and the Eustachian tube is functional (especially fixation of the ossicles due to infectious, traumatic, or congenital causes) result in a conductive loss of hearing in common with otosclerosis. These conditions are therefore sometimes given the designation "pseudo-otosclerosis" (Goodhill, 1960) and they can provide difficulties in the differential diagnosis.

The following points will be of diagnostic significance:

1 Anamnesis. The patient's history may often include information which can lead to a diagnosis.

Information about any familiar tendency toward a loss of hearing will be significant. Such a tendency will support a diagnosis of otosclerosis. The point in time at which the hearing loss apparently began may also aid the diagnosis, as otosclerosis begins, as a rule, during the second decade of life. Information about a lack of tinnitus, and a purely one-sided loss of hearing, can also provide grounds to suspect an ossicular defect.

A conductive loss of hearing of permanent and stable character following upon a cranial trauma, will naturally lead to a suspicion of ossicular luxation or fracture. However the ossicles may be prevented from functioning properly due to fixation by a bone fragment (e.g. a fracture through the area of the tegmen tympani may have this type of effect), a traumatic stenosis of the Eustachian tube or adhesions in the tympanic cavity following a hemotympanum will likewise lead to a conductive loss of hearing.

A permanent loss of hearing in connection with a mastoidectomy or a lesion through the external meatus will indicate as a rule, a luxation of the incus. A conductive loss of hearing after otitis media, with the tympanic membrane remaining intact, will often be caused by a fibrous degeneration of the long process of the incus and/or the stapes crura, but it may just as well be due to an infection being followed by a fixation of the ossicles (adhesions, tympano-sclerosis, etc.)

Now and then, one may receive patients who are unable to recall any details of the incidence of otitis media, while their tympanic membranes bear the imprint of the infection (calcium deposits, fibrosis, atrophic or retracted zones). It must be natural to assume that these persons have suffered from an otitis media during their early childhood, and that the loss of hearing is therefore probably due to a defect in the ossicles, perhaps an infection-caused fixation of one or more of the bones.

Patients having a conductive loss of hearing which already has been observed during their childhood should be suspected of having an ossicular deformity especially where there is a unilateral loss of hearing and/or the patient is found to harbour other anomalies.

At times, patients are found to have defects in the auditory ossicles, while the anamnesis does not indicate any of the above-mentioned causes, and where the hearing loss has developed gradually and the tympanic membrane is quite normal. (As previously mentioned, Escher and Neiger (1963) have called this condition aspheric necrosis of the ossicles)

2. Otoloscopic Examination. In the case of ossicular lesions of traumatic nature, the tym-

10 Defects of the Auditory Ossicles

1 Cases where the deformity is discovered accidentally during an explorative tympanotomy performed because of a suspected otosclerosis.

2 Cases where superficial deformities such as a slight facial asymmetry, unequal functioning of the lower branch of the facial nerve, preauricular fistula, accessory auricular appendages, asymmetry of the external ear, or a slight atrophy of the mandibula permit the preoperative assumption that the conductive loss of hearing is caused by a deformity in the ossicles. A slight narrowing of the meatus, perhaps with exostoses, or a thickened tympanic membrane with a widened handle of the malleus, should also be mentioned in relation to the above.

3 Cases, especially among children, where there may be a pre-operative suspicion of an ossicular deformity based upon the indication of a severe unilateral nonprogressive conductive loss of hearing.

One, two, or all three of the auditory ossicles may be deformed (Hough 1963).

Malleus. The handle of the malleus may be lacking, and an insufficient development of the articulation between the incus and malleus has likewise been observed. The head of the malleus may be larger than normal and thus come in intimate contact with the tegmen tympani where it may become ossified to the roof of the epitympanic recess (Altmann, 1955; Müdnich, 1965).

Incus. There may be hypoplasia (De Witt 1958) or the incus may be totally lacking (Hajek, 1961). The lenticular process may be completely absent, or replaced by a fibrous band (Henner 1960). The same may be true

for a greater or lesser portion of the long process of the incus (Hough, 1958; Tolan and Wilson 1958; Hajek, 1961). It must be emphasized, however, that it may be difficult to determine whether a defect in the long process is post-infectious or congenital.

Stapes. Of the three ossicles, the stapes is reported to be most subject to congenital deformities. This will most often consist in a fixation of the stapes footplate (House et al., 1958) due to insufficient development of the annular ligament, but a complete lack of the oval window may be observed (Gundersen, 1967). Insufficient development of one (Hough, 1958) or both stapes crura (Henner 1960) may also be observed.

Occasionally a partial or total fusion of all three of the ossicles is described (Hough, 1958; Hajek, 1961) as is the fusion of the malleus to the incus alone (Henner 1960).

Together with the ossicle deformities, one may find an abnormal routing of the facial nerve, large dehiscences in the bony facial canal (Hough 1963; Scheer 1967) or the development of the pyramidal eminence, the stapedius tendon, and the round window may be lacking.

VI Auditory Ossicle Defects of Unknown Aetiology

Now and then an explorative tympanotomy will disclose a fibrous degeneration of the long process of the incus and/or the stapes crura where neither the anamnesis nor the objective indications provide a basis for suspecting one of the above-mentioned conditions as being causative. Escher and Neiger (1963) have given such conditions the designation "aspecific bone necrosis".

A necessary condition is that the malleus is mobile. A defect in the ossicular system may permit excessive mobility of the malleus. This allows a stronger registration of the tensor reflex than is normal (which may for example, be observed on the screen of an oscilloscope) as reported by Rietjens (1953). It must be assumed that a normal reflex is demonstrable in the opposite ear. Quantitative impedance measurements will probably provide valuable information about the condition of the ossicular system, especially relating to the differential diagnosis between fixations and defects.

5. An Acoustic Probe. This method (Zöllner 1951; Thullen, 1955) will probably be able to provide information permitting differentiation between defects and fixations in the ossicular system. The author has no experience with this method of examination.

6. Radiological Examination. Of the conventional X-ray projections, two have been shown to be significantly more effective in providing information about the state of the ossicles: The trans-orbital and the Chausse III. However these projections can only provide information about the worst deformities, or about luxations which result in considerable separations between the ossicles (Andersen et al. 1962). Of 31 patients, all having defective ossicular systems, ten displayed pathological

conditions in X-ray examinations using the above-mentioned projections.

Tomographical X-ray examinations can provide additional information about the condition of the ossicles (Mündnich and Frey 1959; Langfeldt, 1963; Bräuner 1964; Valvassori, 1967). Using this technique Andersen et al., (1962) found pathological changes in the ossicular system in 16 of 21 patients, but only 11 of these radiological examinations were fully confirmed during the subsequent operations. In all of these cases, deformities or luxations of the incus or the malleus were disclosed. On the other hand, tomographical examination was revealed to be less valuable in cases of slight dislocations or defects localized in the incudo-stapedial articulation. But, as it will be shown in the Clinical Report II (see below), the tomographic X-ray examination has provided increasingly accurate information on the condition of the ossicles.

7. Tympanotomia Explorativa. As it may be seen from the material noted above, it can be difficult to provide pre-operative verification of a diagnosis of a defective ossicular system, even though this condition will often be suspected.

In numerous cases, a final diagnosis can only be reached during the explorative tympanotomy.

panic membrane will often be more or less cicatricial, especially the upper posterior sector of the drum. Now and then it may be possible—especially with the aid of an operating microscope—to see through an atrophically translucent tympanic membrane and discern a luxation of the incudostapedial joint (Escher 1964).

Changes in the nature of the tympanic membrane in form of thickening, calcium deposits atrophic or retracted zones will often be seen when defects in the ossicles have developed after the ravages of otitis media.

It should be noted that an examination of the mobility of the malleus and the tympanic membrane, using Siegle's speculum may provide information concerning the condition of the ossicles.

3 Audiometric Examination The configuration of the typical otosclerosis audiogram is well known indicating a greater conductive loss for the low frequencies than for the high frequencies. In addition there is a drop in the bone-conduction curve at a maximum of about 2000 Hz (Carhart's Notch). The severity of the otosclerosis, and the extent to which the cochleae have been modified by it, will have a very considerable effect upon the configuration of the tone audiogram.

In the case of a total disruption of the ossicular system with an intact tympanic membrane, the conductive loss of hearing could theoretically amount to approximately 60 dB (Wullstein 1960) throughout the entire frequency range. A hearing loss of this order is also seen now and then, no matter what the aetiology of the defective ossicles may be. It must be emphasized however that the conductive hearing loss following these middle ear diseases can vary greatly as reported by Does and Bottema (1965). They found that a less severe hearing loss than might be expected could be caused by an adhesion formed between the stapes and the long process of the incus, the handle of the malleus, and the tympanic membrane. Furthermore, they found

several cases among their series of traumatically-caused ossicular defects where a perceptive high frequency hearing loss, or "dip" was displayed at C.

Bauer (1964) provides the following audiometric characteristics for defects in the auditory ossicle system with an intact tympanic membrane.

1 A conductive hearing loss of approximately 50 dB in the speech-frequency range,

2. The bone-conduction and the air-conduction curves for the greater part, follow parallel paths throughout the entire frequency range,

3 Carhart's Notch is not found in the bone conduction curve.

4 Impedance Tests. Testing for changes in the impedance of the tympanic membrane—using an acoustic bridge (Metz, 1946) an electro-acoustic apparatus (Terhildsen and Scott Nielsen, 1960) or devices making use of the cross-coupling principle (Neergaard et al 1965)—can occasionally provide valuable information about the state of the ossicles.

A stapedius reflex caused by an acoustic stimulus (Jepsen 1955) or a cutaneous reflex stimulated by the direction of a stream of air upon the outer ear (Djupestrand 1961) can be registered by the change occurring in the impedance of the tympanic membrane, but one of the conditions for this change is a functional, mobile ossicular system. A defective or fixed ossicular system as a rule, will hinder or prevent the transmission of the contraction of the stapedius muscle along the ossicles, thereby changing the impedance of the tympanic membrane. However it will be possible to record a stapedius reflex if the interruption in the ossicular system lies medially to the insertion of the stapedius tendon. In general this will indicate a fracture of the stapes crura (Rietjens, 1963 Andersen and Elbrond 1968). A contraction of the tensor tympani muscle can be stimulated by directing a stream of air against the eyes. This reflex can also be registered through a change in the impedance of the tympanic membrane (Klockhoff 1961).

A necessary condition is that the malleus is mobile. A defect in the ossicular system may permit excessive mobility of the malleus. This allows a stronger registration of the tensor reflex than is normal (which may for example, be observed on the screen of an oscilloscope) as reported by Røtjens (1953). It must be assumed that a normal reflex is demonstrable in the opposite ear. Quantitative impedance measurements will probably provide valuable information about the condition of the ossicular system, especially relating to the differential diagnosis between fixations and defects.

5. An Acoustic Probe. This method (Zöllner 1951; Thullen, 1955) will probably be able to provide information permitting differentiation between defects and fixations in the ossicular system. The author has no experience with this method of examination.

6. Radiological Examination. Of the conventional X-ray projections, two have been shown to be significantly more effective in providing information about the state of the ossicles. The trans-orbital and the Chausse III. However these projections can only provide information about the worst deformities, or about luxations which result in considerable separations between the ossicles (Andersen et al., 1962). Of 31 patients, all having defective ossicular systems, ten displayed pathological

conditions in X-ray examinations using the above-mentioned projections.

Tomographical X-ray examinations can provide additional information about the condition of the ossicles (Mündnich and Frey 1959; Langfeldt, 1963; Brønner 1964; Valvassori, 1967). Using this technique, Andersen et al., (1962) found pathological changes in the ossicular system in 16 of 21 patients, but only 11 of these radiological examinations were fully confirmed during the subsequent operations. In all of these cases, deformities or luxations of the incus or the malleus were disclosed. On the other hand, tomographical examination was revealed to be less valuable in cases of slight dislocations or defects localized in the incudo-stapedial articulation. But, as it will be shown in the Clinical Report II (see below) the tomographic X-ray examination has provided increasingly accurate information on the condition of the ossicles.

7. Tympanotomia Explorativa. As it may be seen from the material noted above, it can be difficult to provide pre-operative verification of a diagnosis of a defective ossicular system, even though this condition will often be suspected.

In numerous cases, a final diagnosis can only be reached during the explorative tympanotomy.

panic membrane will often be more or less cicatricial especially the upper posterior sector of the drum. Now and then it may be possible—especially with the aid of an operating microscope—to see through an atrophically translucent tympanic membrane and discern a luxation of the incudostapedial joint (Escher 1964).

Changes in the nature of the tympanic membrane in form of thickening, calcium deposits, atrophic or retracted zones will often be seen when defects in the ossicles have developed after the ravages of otitis media.

It should be noted that an examination of the mobility of the malleus and the tympanic membrane using Siegle's speculum, may provide information concerning the condition of the ossicles.

3 Audiometric Examination The configuration of the typical otosclerosis audiogram is well known indicating a greater conductive loss for the low frequencies than for the high frequencies. In addition, there is a drop in the bone-conduction curve at a maximum of about 2000 Hz (Carhart's Notch). The severity of the otosclerosis, and the extent to which the cochlea have been modified by it, will have a very considerable effect upon the configuration of the tone audiogram.

In the case of a total disruption of the ossicular system with an intact tympanic membrane the conductive loss of hearing could theoretically amount to approximately 60 dB (Wallstein 1960) throughout the entire frequency range. A hearing loss of this order is also seen now and then, no matter what the aetiology of the defective ossicles may be. It must be emphasized, however, that the conductive hearing loss following these middle ear diseases can vary greatly as reported by Does and Bottema (1965). They found that a less severe hearing loss than might be expected could be caused by an adhesion formed between the stapes and the long process of the incus, the handle of the malleus, and the tympanic membrane. Furthermore, they found

several cases among their series of traumatically-caused ossicular defects where a perceptive high frequency hearing loss, or "dip" was displayed at C.

Bauer (1964) provides the following audiometric characteristics for defects in the auditory ossicle system with an intact tympanic membrane.

1 A conductive hearing loss of approximately 50 dB in the speech-frequency range.

2 The bone-conduction and the air-conduction curves, for the greater part, follow parallel paths throughout the entire frequency range.

3 Carhart's Notch is not found in the bone conduction curve.

4 Impedance Tests. Testing for changes in the impedance of the tympanic membrane—using an acoustic bridge (Metz, 1946) an electro-acoustic apparatus (Terklidsen and Scott Nielsen, 1960) or devices making use of the cross-coupling principle (Neergaard et al., 1965)—can occasionally provide valuable information about the state of the ossicles.

A stapedius reflex caused by an acoustic stimulus (Jepsen, 1955) or a cutaneous reflex stimulated by the direction of a stream of air upon the outer ear (Djupestrand 1961) can be registered by the change occurring in the impedance of the tympanic membrane but one of the conditions for this change is a functional, mobile ossicular system. A defective or fixed ossicular system as a rule will hinder or prevent the transmission of the contraction of the stapedius muscle along the ossicles, thereby changing the impedance of the tympanic membrane. However it will be possible to record a stapedius reflex if the interruption in the ossicular system lies medially to the insertion of the stapedius tendon. In general this will indicate a fracture of the stapes crura (Rietjens, 1963 Andersen and Elbrond, 1968). A contraction of the tensor tympani muscle can be stimulated by directing a stream of air against the eyes. This reflex can also be registered through a change in the impedance of the tympanic membrane (Klockhoff, 1961).

2. **Bone Fragments.** Pieces of bone from the wall of the meatus and the mastoid cortex appear to be finding increased use in reconstructive auto-transplantation in the middle ear. In experiments with animals (guinea pigs and dogs), it has been demonstrated that auto-transplanted bone fragments can remain vital in the middle ear (Beck and Franz, 1961; Guilford et al., 1966). Beck and Franz (1961) have likewise demonstrated that changes in the dimensions of the bone fragments takes place so that the form may be altered and a certain amount of thickening may occur. These same authors also found that three auto-transplanted bone fragments in the middle ear were satisfactorily nourished from a histological point of view.

Kley and Draf (1965) have also demonstrated that auto-transplanted bone fragments have been covered by mucous membrane, that the internal structure has been retained and the nuclei of osteocyte cells were clearly stained in microscopic slides, and that the connective tissue filling the spaces within the bone was prolific and well vascularized. In one case, during a re-operation for otosclerosis, the author extirpated a piece of bone which had been implanted in the middle ear six years previously and which had served as columella between the tympanic membrane and the oval window. The bone had macroscopically retained its structure. Microscopic examination revealed that the bone was covered by a mucous membrane, and that there were osteocytes in the periphery of the bone, but not in the central part of the section. However the central part did not show any signs of degeneration. This bone fragment could thus have continued its role as acting columella.

3. **Cartilage** has been used by Utech (1961) and Pfaltz and Meyer (1966) in auto-transplants, and they seem to retain their cartilaginous structure both macroscopically and microscopically. This was confirmed by Utech (1961) upon re-operation 12 months after implantation.

Smyth et al., (1967) make use of both auto-transplants and homo-transplants as prostheses in the middle ear. The homologous cartilage was acquired by resection of the nasal septum. They have found that both kinds of cartilage react identically in the middle ear of man and animal (cats). The cartilage remains normal macroscopically while microscopic examination shows that the cartilaginous tissue lacks vital cells, but the normal mucous membrane has covered the implant.

B Foreign Bodies

1 Polyethylene, Teflon, Steel, Tantulum, Gold, and Platinum

Prostheses of the above-named non-biological materials have been implanted in thousands of middle ears. According to Bennett (1963) there are no published records of the development of cancer in human patients after the implantation of plastic materials. However, fibro-sarcoma-like tumours may be seen to develop in experimental animals (rats) one to two years after the subcutaneous implantation of plastic materials (Oppenheimer et al., 1955). Hohnmann et al., (1964) found that the development of such tumours depended upon the area of the plastic surface in contact with the tissue. It is their belief that the contact surfaces of the plastic prostheses implanted in the middle ear are so small as to eliminate any chance of the development of cancer.

Anthony (1963) has subcutaneously implanted pieces of the following materials, having dimensions corresponding to those of middle-ear prostheses, in an experimental subject. Polyethylene tube, teflon columella, steel wire, and tantulum wire. Histological examination eight and one half months later disclosed the presence of fibrosis surrounding all four materials. Furthermore, a slight chronic inflammation and giant-cell reaction was found around the teflon prosthesis.

Goldman et al., (1962) found, however, that teflon produced less reaction in cats' ears than did polyethylene, palladium, supramid, or steel.

SURGICAL TREATMENT

Review of the Literature

The object of surgical treatment of defects in the auditory ossicles must be to restore to the greatest extent possible, the function of the middle ear as an organ for the transformation of sound waves.

It is commonly accepted that the deciding factor in this function is the difference between the size of the effectively vibrating sector of the tympanic membrane and the size of the stapes footplate. On the other hand the leverage effects between the auditory ossicles are of very little importance when compared to the total sound pressure transformation.

The replacement of the complicated bony lever system by a single bone (columella) connecting the tympanic membrane with the oval window which is the natural construction of the ear among the birds, or by a direct connection between the tympanic membrane and the head of the stapes (myringo-stapedio-pexi) will theoretically result in a hearing loss of only 2.5 dB which is for practical purposes an insignificant loss of hearing.

The immediate aim of a surgical operation will therefore in most cases, primarily be concerned with the creation of a columella between the tympanic membrane and the stapes or the stapes footplate. A secondary goal will be the restoration of the normal functioning of the auditory ossicles, to that extent where this is possible.

Before the reconstructive surgical treatment of the defective ossicles is described, the biological properties of the materials used for prostheses must be related.

The following materials have been used in the reconstruction of the ossicles, or in the creation of a columella.

A. Auto and Homo Tissue Transplantation Material

I Ossicle Fragments. The remains of the incus and the malleus are often used in the reconstruction of a defective ossicular system. Reoperation has shown that auto-transplanted remains of the ossicles have been covered by mucous membrane, and that they have retained their original form. Microscopic examination has shown that there is no degeneration the ossicles retain their bone structure. Even though some of the central cancellous spaces in these ossicles may become enlarged, they contain vital connective tissue and blood filled capillaries (Hall and Rytznér 1960 Kley and Draf 1965).

Homo-transplanted ossicles (incus) have been used by House et al (1966). In 28 cases, they used the incus from patients who were operated upon for acoustic tumours. None of the transplants were complicated by infection. In one case the incus was rejected through a transplant tympanic membrane taken from the wall of the meatus. This incus may have been rejected because of a retraction of the tympanic membrane transplant. Both the macroscopic and the microscopic examination of this incus provided evidence to support the assumption that the bone was vital. Pulec (1966) has also made use of homo-transplanted ossicles (incus) in 22 cases. It became necessary to re-operate three patients after some months. In each of the three cases, the incus was found to have a normal appearance and form when examined macroscopically and each was covered with mucous membrane. However the microscopic examination failed to reveal any sign of living cells within the bones.

2. **Bone Fragments.** Pieces of bone from the wall of the meatus and the mastoid cortex appear to be finding increased use in reconstructive auto-plantation in the middle ear. In experiments with animals (guinea pigs and dogs) it has been demonstrated that auto-transplanted bone fragments can remain vital in the middle ear (Beck and Franz, 1961; Guilford et al., 1966). Beck and Franz (1961) have likewise demonstrated that changes in the dimensions of the bone fragments takes place, so that the form may be altered and a certain amount of thickening may occur. These same authors also found that three auto-transplanted bone fragments in the middle ear were satisfactorily nourished from a histological point of view.

Kley and Draf (1965) have also demonstrated that auto-transplanted bone fragments have been covered by mucous membrane, that the internal structure has been retained and the nuclei of osteocyte cells were clearly stained in microscopic slides, and that the connective tissue filling the spaces within the bone was prolific and well vascularized. In one case, during a re-operation for otosclerosis, the author extirpated a piece of bone which had been implanted in the middle ear six years previously and which had served as columella between the tympanic membrane and the oval window. The bone had macroscopically retained its structure. Microscopic examination revealed that the bone was covered by a mucous membrane, and that there were osteocytes in the periphery of the bone, but not in the central part of the section. However the central part did not show any signs of degeneration. This bone fragment could thus have continued its role as acting columella.

3. **Cartilage** has been used by Utech (1961) and Pfaltz and Meyer (1966) in auto-transplants, and they seem to retain their cartilaginous structure both macroscopically and microscopically. This was confirmed by Utech (1961) upon re-operation 12 months after implantation.

Smyth et al., (1967) make use of both auto-transplants and homo-transplants as prostheses in the middle ear. The homologous cartilage was acquired by resection of the nasal septum. They have found that both kinds of cartilage react identically in the middle ear of man and animal (cats). The cartilage remains normal macroscopically while microscopic examination shows that the cartilaginous tissue lacks vital cells, but the normal mucous membrane has covered the implant.

B Foreign Bodies

1 Polyethylene, Teflon, Steel, Titanium Gold, and Platinum

Prostheses of the above-named non-biological materials have been implanted in thousands of middle ears. According to Bennett (1963) there are no published records of the development of cancer in human patients after the implantation of plastic materials. However fibro-sarcoma-like tumours may be seen to develop in experimental animals (rats) one to two years after the subcutaneous implantation of plastic materials (Oppenheimer et al., 1955). Hohmann et al., (1964) found that the development of such tumours depended upon the area of the plastic surface in contact with the tissue. It is their belief that the contact surfaces of the plastic prostheses implanted in the middle ear are so small as to eliminate any chance of the development of cancer.

Anthony (1963) has subcutaneously implanted pieces of the following materials, having dimensions corresponding to those of middle-ear prostheses, in an experimental subject: Polyethylene tube, teflon columella, steel wire, and tantalum wire. Histological examination eight and one half months later disclosed the presence of fibrosis surrounding all four materials. Furthermore, a slight chronic inflammation and giant-cell reaction was found around the teflon prosthesis.

Gokman et al., (1962) found, however that teflon produced less reaction in cats ears than did polyethylene, palladium, supramid, or steel.

Hough (1965) states that polyethylene can produce a slight inflammatory reaction in the mucous membrane and that necrosis of the incus may result

Koide (1965) reports that polyethylene produces a vigorous foreign-body reaction in an infected middle ear but that it is inactive in uninfected middle ears.

Schuknecht and Oleksiuk (1960) introduced the use of metal wire to otosclerotic surgery and they have demonstrated that both tantalum and steel wire are well tolerated in the middle ears of both experimental animals and in man. The prostheses were covered by mucous membrane and did not produce foreign-body reactions.

Mehmke (1966) has found on using gold and platinum wire, that these materials are well tolerated in the middle ear.

Reconstructive Surgery on the Defective Auditory Ossicles

Zöllner's and Wullstein's work on tympano-plastic surgery of the middle ear triggered significant interest in this type of reconstructive operation.

Before these authors published only very few had attempted reconstructive surgery on the middle ears sound transmission mechanism but since then, numerous authors have been concerned with the problems arising in connection with such operations.

A significant number of suggested ossiculo-plastic surgical treatments have been brought to light during the course of years.

The ossiculo-plastic operation which is selected will to a certain degree, depend upon the type and localization of the defect in the individual case being treated.

The following methods of reconstructing the defective auditory ossicles will be described

- 1 Myringo-stapedio-pecti
- 2 Reposition of ossicular luxations and fractures
- 3 Interposition of prostheses
- 4 Transposition of ossicles

1 Myringo-stapedio-pecti

This technique restores the functional transmission of sound by establishing contact between the tympanic membrane and the head of the stapes. The technique can thus be used when the incus is defective or lacking, but the stapes is still intact and mobile. It was used as early as 1901 by Matte, but was then neglected until taken up again by Zöllner and Wullstein for use in radical operations with partly or wholly preserved tympanic membranes (Tympano-plastic Type III). Jers (1954) has made use of the term "myringo-stapedio-pecti" to designate this operation.

Numerous authors have published reports on the functional results of Type III tympano-plastic operations in cases of chronic otitis media (Zöllner 1966) but only a few have published the results of myringo-stapedio-pecti procedures used on patients with defective ossicles and an intact tympanic membrane. Hamburger and Lidén (1958) have made use of transmeatal myringo-stapedio-pecti in 12 cases where the incus was more or less defective or dislocated and where the tympanic membrane remained intact. In nine cases, an improvement in hearing was achieved, with a threshold of hearing of 30 dB or less. It is stated that it was necessary to loosen the skin within the external meatus, the annulus, and the tympanic membrane to the extent to about two thirds of the circumference in order to achieve contact between the tympanic membrane and the head of the stapes. In some cases, it was necessary to sever the neck of the malleus and the tendon of the tensor tympani muscle in order to make the tympanic membrane's contact with the head of the stapes easier.

Several authors (Pick, 1957 Thorburn, 1957 Williams, 1958 Bauer 1958 Hough 1959 Flisberg and Floberg, 1960 Risker 1960 Hammond 1964 Escher 1964) have achieved good improvements in hearing using this technique. The authors mentioned have only published a single or very few cases each however.

It is therefore evident that it is possible to achieve satisfactory improvement in hearing with the myringo-stapedio-pecti technique, but it is doubtful that satisfactory results can be reproduced with the required frequency. Guilford (1964) reports that in using this technique: 1. It is difficult to retain the posterior wall of the external meatus as the tympanic membrane must be brought into contact with the head of the stapes; 2. It is difficult to ensure a stable and adequate connection between the tympanic membrane and the head of the stapes; 3. It is difficult to ensure a sufficiently large air-filled space in the tympanic cavity as adhesions of the tympanic membrane to the promontory often occur. Finally he notes that a contributory cause of the inefficiency of this method can be the columella's position at the edge of the membrane. For these reasons, most authors seem to have given up myringo-stapedio-pecti in favour of repositioning, interpositioning, or transpositioning methods.

1. Reposition

In the case of an isolated incus luxation, one of the first methods of treatment to be considered will be a repositioning. This can only be performed with expectation of improved hearing when the lenticular process can easily be brought into contact with the head of the stapes, and when the articulation between the incus and the malleus is functional or can be made to function. Several authors (Pfeister 1957, Gieschen, 1958, Hough, 1959, Ellaberg and Floberg, 1960, Escher 1964, Does and Bottema, 1965) have reported successful repositioning of this sort, with good improvement in hearing as a result, especially in the lower frequencies (Riskier 1960). But a repositioning which initially appears to have been successful is not always followed by an improvement in hearing (Does and Bottema, 1965, Bicknell, 1966) or an improvement may later regress (Schuknecht and Trupiano 1967). One possible explanation for this retrogression

may be that the incudo-stapedial joint had not formed a sufficiently stable bond, and that the lenticular process has again lost contact with the head of the stapes. In order to stabilize the joint, Escher (1964) has made use of a little polyethylene prosthesis placed over the joint in a single case. Stabilization of the joint with a little segment of vein drawn over the joint, as described by Dietzel (1963) could possibly be expedient.

Repositioning of a dislocated malleus will presumably be successful only very rarely. Escher (1964) has reported a single case, but there was only a slight improvement in the patient's hearing.

A repositioning of a fractured and dislocated stapedial arch can infrequently be carried out successfully (Andersen and Elbrynd, 1968). In this case, which is also included as a report in a later part of this paper, the stapedial arch was luxated down to the promontory but the stapedius tendon and the incudo-stapedial joint were partially intact. A little fragment of the footplate was fastened to the anterior crus, which was the reason for the stability of the repositioning. Normal hearing was attained.

3. Interposition

This term includes the insertion of auto- or homo-transplanted ossicles, pieces of bone or cartilage or prostheses made of non-biological material to bridge a defect in the ossicular system or to function as a columella.

a. In the case of a defective lenticular process, or a slight luxation which cannot be repositioned, pieces of bone (Hough, 1959, Beickert, 1962, Andersen et al., 1962, Buchheim, 1966) or pieces of cartilage (Pfaltz and Meyer 1966) can be interposed between the long process of the incus and the head of the stapes. However the results of an interposition of pieces of bone are unreliable according to Zöllner (1966). The interposition of polyethylene tubing has been used by Sooy (1960). Hall

et al (1960) Hammond (1964) and Escher (1964) with good results, but Kley (1966) points out that in spite of the immediately good results, there is a possibility of subsequent loss of hearing due to pressure necrosis of the lenticular process and the stapes head. This sort of effect has been observed by Ballantyne (1962) who on one occasion achieved a 50 dB improvement in hearing through the interposition of a little polyethylene tube between the long process of the incus and the stapes head. After approximately six months hearing began to deteriorate again and after about one year approximately half of the improvement had been lost. Upon re-operation, the head and neck of the stapes were found to be necrotic. A stapedectomy according to Schuknecht's method was then performed. In one case of an incus luxation which could not be repositioned, Kossner (1961) interposed between the head of the stapes and the long process of the incus a piece of polyethylene tube of such a length that the long process was pressed outward into contact with the tympanic membrane. An exceptionally good improvement in the hearing function was achieved.

b In the case of defects of the long process of the incus as well renewed function can be achieved through use of a steel wire prosthesis having an "eye" fitting the long process and connecting with the stapes head (Oppenheimer and Harrison 1963). The normal leverage effect can be re-established in this manner but it is noted that if the wire is pressed too tightly around the long process and the stapes head there may be necrosis and the prosthesis may then slip out of position. There are no reports of the results achieved with this method. The "phonograph" type of prosthesis (a steel wire with an "eye" loop is fastened to the long process, and the other end inserted into the excavated head of the stapes) has been reported to give good results (Oppenheimer and Harrison 1963). Combinations of polyethylene and steel wire are also used for the repair of defects of this type (Harrison and Shambaugh

1959). It is stated that these types of prostheses are especially effective in the relatively low frequency range, but there is no mention of observation periods. These prostheses will presumably be extremely difficult to install in a satisfactory manner.

Mehmke (1966) makes use of gold and platinum wire prostheses in a similar manner. He additionally describes a gold clip which can be pressed down over the long process and the head of the stapes in cases of a defective lenticular process. Polyethylene tube prostheses which can be pushed up over the defective long process, and with the other end in contact with the stapes head—if necessary this end of the tube may be bent so that it will fit over the stapes head—have been used by Harrison and Shambaugh (1969), Sooy (1960) and Oppenheimer and Harrison (1963) with at least initially good results. In addition to the difficulty experienced in inserting these prostheses, it must be expected that they can produce necrosis of the long process and the head of the stapes. This author has observed such a necrosis of the long process of the incus after the insertion of a polyethylene-tube prosthesis (Elbrod and Elpern 1965).

In cases where the long process of the incus is lacking a columella effect can be achieved by interposing a prosthesis between the head of the stapes and the tympanic membrane or the handle of the malleus. A method reported by numerous authors to be suitable for the creation of such a columella effect is the interposition of the body of the incus between the stapes head, the handle of the malleus, and the tympanic membrane (Andersen et al., 1962; Portmann 1963; Guilford 1964, 1966; House and Sheehy 1963; Steffen 1964; Chandler 1965; Sheehy 1965; Perrét, 1966; Smyth et al. 1967).

The first to have used auto-transplanted incus (and malleus head) were Hall and Rytznér (1957).

Guilford (1966) makes use of the following technique: The incus is extracted and inspected. Thereafter the incus is replaced in the middle

ear so that the previously lateral surface now rest on the head of the stapes. Should there be a stump of the lenticular process still affixed to the stapes head, this fragment is removed first, in order to secure the best possible contact surface for the incus. The apex of the short process is positioned under the handle of the malleus with the shortened long process lying parallel with the handle. The incus is supported in this position with spongostan. Finally the tympanic membrane is tamponed into contact with the incus. In 28 cases where this technique was used, an average hearing improvement of 23.2 dB was achieved, and 86.5 per cent of these patients achieved a threshold of hearing of 30 dB or better. However myringo-plastic operations had been performed in at least a part of this group. House and Sheehy (1963) also report that they have achieved the best results by interposing the incus between the stapes, the handle of the malleus, and the tympanic membrane. Smyth et al. (1967) report that in 70 per cent, or 85 ears, where this technique was attempted, the air-bone gap was reduced to 10 dB or less.

c In cases where the incus totally lacking, the excised head of the malleus can be interposed between the head of the stapes, the malleus handle and the tympanic membrane (Portmann, 1963; Mehmkke, 1964; Sheehy 1965).

The columella interposition of shaped bone fragments between the stapes head and the handle of the malleus, or between the stapes head and the tympanic membrane, was used by Zöllner (1960), especially in cases where conditions were not suitable for a myringo-stapedio-pecti. By interposing the shaped bone fragment as described by Zöllner (he calls this a columellization") it is possible to avoid the flat tympanic cavity and resultant difficulties which follow a myringo-stapedio-pecti. Zöllner (1960) has additionally described a technique for excising bone columella of the optimal shape and size from the cortex of the mastoid process. Others as well (Andersen et al 1962; Sheehy 1965; Bauer 1966) have

successfully made use of a bone columella in treating defects of this type. With this technique, Bauer (1966) has secured an average improvement in hearing of 23.6 dB in a group of 16 patients. However these patients had also been treated with myringo-plastic operations using fascia.

The interposition of pieces of cartilage has been used by Utech (1961) and Pfaltz and Meyer (1966) in defects of this type, with good results.

Polyethylene and teflon prostheses with various shapes (see below) can be interposed between the head of the stapes and the tympanic membrane (Sheehy 1965; Austin, 1965) or between the head of the stapes and the handle of the malleus (Does and Bottema, 1965) with relative ease, but a not insignificant percentage of the cases where the prosthesis is placed against the tympanic membrane will sooner or later result in a perforation at this point. Guilford (1964) has used teflon prostheses from the head of the stapes to the tympanic membrane, or a transplant, in 17 cases. He achieved an average improvement in hearing of 9.7 dB. The series is skewed, however by one case having a hearing loss of 35 dB.

When the incus is defective, or totally lacking, Gundersen (1964) has used an incus prosthesis, i.e. an accurate polyethylene model of a normal incus. This polyethylene incus is held in place with a little steel clip which grips the neck of the malleus. The articulation with the head of the stapes is ensured by use of a little polyethylene tube. Should the stapedial arch be lacking, the polyethylene tube can be extended to articulate with the stapes footplate. Gundersen (1964) has used this prosthesis in 20 cases. He states that the results, in regard to improvement in hearing, have been encouraging, but he provides no other results.

Metal wire prostheses (tantalum, steel, gold, or platinum) connecting the handle of the malleus to the head of the stapes (malleo-stapedio-pecti) have been used by Oppenheimer and Harrison (1963) and Mehmkke (1966)

et al (1960) Hammond (1964) and Escher (1964) with good results, but Kley (1966) points out that in spite of the immediately good results, there is a possibility of subsequent loss of hearing due to pressure necrosis of the lenticular process and the stapes head. This sort of effect has been observed by Ballantyne (1962) who on one occasion achieved a 50 dB improvement in hearing through the interposition of a little polyethylene tube between the long process of the incus and the stapes head. After approximately six months, hearing began to deteriorate again, and after about one year approximately half of the improvement had been lost. Upon re-operation, the head and neck of the stapes were found to be necrotic. A stapedectomy according to Schuknecht's method was then performed. In one case of an incus luxation which could not be repositioned, Kossner (1961) interposed between the head of the stapes and the long process of the incus a piece of polyethylene tube of such a length that the long process was pressed outward into contact with the tympanic membrane. An exceptionally good improvement in the hearing function was achieved.

b In the case of defects of the long process of the incus as well renewed function can be achieved through use of a steel wire prosthesis having an "eye" fitting the long process and connecting with the stapes head (Oppenheimer and Harrison, 1963). The normal leverage effect can be re-established in this manner but it is noted that if the wire is pressed too tightly around the long process and the stapes head there may be necrosis and the prosthesis may then slip out of position. There are no reports of the results achieved with this method. The "phonograph" type of prosthesis (a steel wire with an "eye" loop is fastened to the long process, and the other end inserted into the excavated head of the stapes) has been reported to give good results (Oppenheimer and Harrison, 1963). Combinations of polyethylene and steel wire are also used for the repair of defects of this type (Harrison and Shambaugh,

1959). It is stated that these types of prostheses are especially effective in the relatively low frequency range but there is no mention of observation periods. These prostheses will presumably be extremely difficult to install in a satisfactory manner.

Mehmke (1966) makes use of gold and platinum wire prostheses in a similar manner. He additionally describes a gold clip which can be pressed down over the long process and the head of the stapes in cases of a defective lenticular process. Polyethylene tube prostheses which can be pushed up over the defective long process, and with the other end in contact with the stapes head—if necessary this end of the tube may be bent so that it will fit over the stapes head—have been used by Harrison and Shambaugh (1969), Sooy (1960) and Oppenheimer and Harrison (1963) with at least initially good results. In addition to the difficulty experienced in inserting these prostheses, it must be expected that they can produce necrosis of the long process and the head of the stapes. This author has observed such a necrosis of the long process of the incus after the insertion of a polyethylene-tube prosthesis (Elbrønd and Elpern, 1965).

In cases where the long process of the incus is lacking, a columella effect can be achieved by interposing a prosthesis between the head of the stapes and the tympanic membrane or the handle of the malleus. A method reported by numerous authors to be suitable for the creation of such a columella effect is the interposition of the body of the incus between the stapes head, the handle of the malleus, and the tympanic membrane (Andersen et al., 1962; Portmann, 1963; Guilford, 1964, 1966; House and Sheehy, 1963; Steffen, 1964; Chandler, 1965; Sheehy, 1965; Perrét, 1966; Smyth et al., 1967).

The first to have used auto-transplanted incus (and malleus head) were Hall and Rytznér (1957).

Guilford (1966) makes use of the following technique. The incus is extracted and inspected. Thereafter the incus is replaced in the middle

body prostheses in the middle ear (Wullstein, 1960).

Similar experiences have been recorded by numerous authors (Brockman, 1961 Hayden, 1961 Piester 1961 Seidentop and Brown, 1966). This continues to be true even where the prostheses are given such a shape as to greatly reduce the tendencies toward perforation of the tympanic membrane or transplant, e.g. "sunflower" or "wire-mesh" prostheses (House and Sheehy 1963 Sheehy 1965).

On the basis of the experiences gained from several hundred operations, Portmann (1967) reports achieving good immediate results following the introduction of polyethylene or teflon, but if these prostheses were inserted in direct contact with the tympanic membrane they were expelled in nearly every case.

Austin (1965) has used teflon prostheses interposed between the stapes footplate and the handle of the malleus in a large number (338) of cases. These prostheses are provided with an "eye" in one end, to permit fastening around the handle. The other end rests on the footplate. In order to make possible the use of this type of prosthesis in cases where the stapedial arch remains intact, Austin (1965) often removes it. He reports that in 63 per cent of 134 cases, this technique has resulted in reductions of the air-bone gap to less than 10 dB. Three per cent of the prostheses were expelled, and 1.8 per cent slipped out of position. Guilford (1964) has used the same type of prosthesis in ten cases with an average improvement in hearing of 24.1 dB. Guilford (1964) draws attention, however to the existing risk of displacement of the stapes footplate when attempting to achieve a satisfactory positioning of the prosthesis while simultaneously retaining the optimal length of the prosthesis. He consequently uses prostheses which are slightly shorter than the distance from the handle of the malleus to the footplate of the stapes, and compensates for the difference by placing small wedge-shaped pieces of bone or tantalum between the prosthesis and the footplate. In addition to the length adjust-

ment, the wedge also reduces the tendency of the somewhat diagonally-positioned prosthesis to slip backwards on the footplate.

Sheehy (1965) uses steel wire prosthesis (IRP- Iocus Replacement Prosthesis) which can be fastened to the handle of the malleus and which can reach the stapes footplate. Using this type of prosthesis, and with polyethylene tube from the malleus to the footplate, he has in 70 per cent of the cases obtained an air bone gap of 20 dB or less, four months after operating. Tabb (1963) has used teflon-coated steel wire prostheses from the stapes footplate to the handle of the malleus or the tympanic membrane. Mehmkie (1966) has used metal wire (of gold or platinum) in a similar manner from the handle of the footplate, and reports achieving good results.

4. Transposition

Transposition is the re-arrangement of ossicles while wholly or partially preserving their suspensory ligaments, articulations, and muscle insertions. In cases of defects in the incus, Westrow (1957) has been able to turn the handle of the malleus sufficiently to bring it into contact with the head of the stapes. The tympanic membrane must first be dissected free of the handle, and the head of the malleus must often be removed, but the tendon of the tensor muscle and the ligaments of the malleus are preserved intact. He states that the primary indication for carrying out a reconstruction of the ossicular system in this manner is the avoidance of the flat tympanic cavity which follows Type III tympano-plastic and myringo-stapedio-pexy, and which involves a significant risk of adhesions between the tympanic membrane and the transplant, or the promontory. He gives no results.

Hall and Rytner (1957), who have used auto-transplantation of the malleus and the incus in otosclerosis operations and with defects in the ossicular system since 1955 have also described transposition of the malleus in connection with defects of the incus and the stape

d In the case of an isolated defect in the stapes or a fracture of the stapes crura, where the remainder of the ossicular system remains functional one of the prosthetic substitutes for the stapes used in connection with stapedectomy (Kley 1966) may serve without the removal of the footplate of the stapes. In two cases of fracture of the stapes, Sadé (1964) has preferred to carry out a stapedectomy according to Schuknecht's method—using a steel wire prosthesis—with good results. Robinson (1961) has also achieved a good result in a case where he performed a stapedectomy according to Shea's method, with the interposition of polyethylene tubing.

Haramond (1964) has made use of platinectomy covering the oval window with a piece of vein followed by interposition of the stapedial arch. Does and Bottema (1965) have interposed connective tissue between the stapedial arch and the stapes footplate, in a case where the stapes crura were fractured at the footplate whereby the air bone gap was reduced from 45 dB to 15 dB. In a case where the crura were fractured during an attempt to mobilize an otosclerotic footplate Meyers (1959) stabilized the fracture with a thin polyethylene tube on the crura. The immediate result was good.

e If the stapedial arch and the tip of the long process of the incus are lacking a columella effect can be achieved by interposing the incus between the handle of the malleus and the stapes footplate or between the tympanic membrane and the footplate (Austin 1965, Sheehy 1965, Chandler 1965). As pointed out by Chandler (1965) and Austin (1965) the length of the incus from the apex of the short process to the middle of the saddle-shaped surface of the articulation is often very nearly the distance from the footplate to the handle of the malleus, so that the incus can be repositioned with the short process on the footplate, and with the handle resting in the saddle-shaped articular surface. If the incus is unstable in this position, small pieces of con-

nective tissue can be positioned around the short process at the footplate.

f In cases where the incus and the stapedial arch (and perhaps the handle of the malleus as well) were totally lacking, Zöllner (1960) and Guilford (1966) have made use of shaped pieces of bone interposed between the footplate and the handle of the malleus. These bone prostheses are provided with notches which fit the handle, thus ensuring positive and stable contact. Bauer (1966) has used bone fragments interposed between the footplate and the tympanic membrane—or a transplant serving as the tympanic membrane—in eight patients. The improvement in hearing averaged 25.3 dB. Two of these patients suffered post-operative infections in the ear but in spite of the infections, the bone transplants were not expelled.

In a similar manner Utech (1961) has made use of cartilage pieces from the auricle. Using pieces of cartilage with attached pericondrium from the tragus Brockman (1965) has altered 30 cases of Type IV tympano-plastic to Type III. He achieved an average improvement in hearing of 16.6 dB. Only four patients did not display any improvement. In only one case there was a partial degeneration of the transplant. Smyth et al., (1967) make use of homologue pieces of cartilage shaped like a boomerang with one end on the footplate of the stapes and with the lateral end shoved in under the handle of the malleus or where the handle is lacking with support at the distal edge of the annulus. They report that this type of prosthesis has reduced the air bone gap to 10 dB or less in 71 per cent of these cases.

Reconstruction of this type of defect is often attempted with prostheses made of foreign-body materials. Wullstein (1956) has attempted to use acrylic prostheses to alter Type IV tympano-plastic to Type III. He reports that he has had some good results from the use of this kind of artificial columella, but he found that they had a tendency to perforate the newly-formed tympanic membrane, for which reason he has since given up the use of foreign-

6. Interposition and transposition methods often produce good results.

7. An evaluation of tabulations of hearing improvements with the object of deciding whether one method or reconstruction is statistically better than another is not quite possible. There are too many variable factors which can influence the reported results, such as the choice of patients, weighing of the indications, surgical experience and technique, the use of local or general anaesthesia, the method of registering the results, the period of observation, etc. It is a question of factors which are often not mentioned.

However the literature survey seems to indicate, in general, that the results of the operations, especially in regard to the permanency of the hearing improvements achieved, have shown betterment in recent years. This seems to be especially true since the remains of ossicles, pieces of bone, and cartilage have increasingly been used as prosthetic materials.

Hearing improvements after reconstructive surgery on the defective auditory ossicle system are not yet fully satisfactory nor are they quite on a par with the results achieved with otosclerotic surgery.

dial arch. The malleus is mobilized by severing the tendon of the tensor muscle and the ligaments, the handle is dissected free of the tympanic membrane except at the umbo and the malleus can then be rotated so that the head fits into the oval niche.

Miodonski (1959 cit by Proctor 1961) has used the following technique. After resection of the head of the malleus, the distal end of the handle is dissected free of the tympanic membrane. The handle can then be rotated so that the umbo can be brought into contact with the head of the stapes.

Rubinstein et al (1962) mobilize the malleus by dissecting it free of the tympanic membrane and severing all of the ligaments, so that the malleus is fixed only by the tendon of the tensor muscle. The malleus can now be rotated at will, so that either the head or the end of the handle of the malleus can be brought into contact with the head of the stapes. They have used this technique on 14 patients. Of these 12 demonstrated hearing improvements of more than 15 dB, the average for these 12 being 28.5 dB and the post-operative air bone gap averaged 12 dB.

Kley (1964 and 1966) also used transposition of the malleus in cases where the incus is defective or lacking. In Malleo-co-stapedio-peri I the head of the malleus is excised directly above the insertion of the tendon of the tensor muscle. The distal part of the handle is dissected free of the tympanic membrane, so that it can be turned and the umbo is then brought into contact with the head of the stapes. In Malleo-co-stapedio-peri II the neck of the malleus is severed just under the insertion of the tendon of the tensor muscle. The head of the malleus is then rotated about the tendon of the tensor muscle until it comes to rest on the head of the stapes.

On rare occasions, where the lenticular process of the incus is defective the incus can be rotated about the posterior ligament of the short process of the incus so that the long process can be brought into contact with the head of the stapes (Zöllner 1955 Farrior 1960).

A necrosis of the lenticular process of the incus can now and then be corrected by tipping the stapes in the oval niche, in the proximal direction so that the head of the stapes contacts the long process. Sadé (1965) has attempted this on seven patients. This slight transposition of the stapes and the resulting contact with the long process of the incus was maintained by placing small wedge-shaped bone fragments in the opening between the stapes and the promontory. Hearing improvement was obtained in six of the cases (averaging about 30 dB).

Farrior (1960) has described transposition of the incus in defects of the long process and the stapedial arch. The short process of the incus was loosened and brought into contact with the stapes footplate without loosening the articulation between the incus and the malleus. Farrior has also made use of malleus transposition.

Conclusions

On the basis of this survey of the literature, it is possible to establish that

1. Prostheses of plastic materials, in most cases, are unsuitable for reconstruction of the defective ossicular system, at least in those cases where the prosthesis is in direct contact with the tympanic membrane. Only rarely is there a lasting improvement in hearing when this type of prosthesis is used.

2. Prostheses of tissue (bone or cartilage) are satisfactory and can produce lasting improvements in hearing.

3. Prostheses of metal wire are satisfactory when they can be fastened around or press against the remnants of the ossicular system.

4. Myringo-stapedio-peri does not seem to provide satisfactory or lasting improvements in hearing with sufficient frequency.

5. Repositioning of dislocated ossicles can now and then produce satisfactory results, but it can be difficult to preserve the reduction, once obtained.

6. Interposition and transposition methods often produce good results.

7. An evaluation of tabulations of hearing improvements with the object of deciding whether one method or reconstruction is statistically better than another is not quite possible. There are too many variable factors which can influence the reported results, such as the choice of patients, weighing of the indications, surgical experience and technique, the use of local or general anaesthesia, the method of registering the results, the period of observation, etc. It is a question of factors which are often not mentioned.

However the literature survey seems to indicate, in general, that the results of the operations, especially in regard to the permanency of the hearing improvements achieved, have shown betterment in recent years. This seems to be especially true since the remains of ossicles, pieces of bone, and cartilage have increasingly been used as prosthetic materials.

Hearing improvements after reconstructive surgery on the defective auditory ossicle system are not yet fully satisfactory nor are they quite on a par with the results achieved with otosclerosis surgery.

CLINICAL REPORT I

Clinical Series I consists of 67 patients who have been operated upon for defects of the auditory ossicle system. Four of these patients have received surgery in both ears. The series thus covers a total of 71 ears.

All of the patients have had intact tympanic membranes, although these were often cicatrized and the middle ear was air filled. The requirement of an intact tympanic membrane was due to the desire for a group of patients where the improvement in hearing (or perhaps the hearing loss) was primarily due to the reconstructive operation on the defective ossicular system.

The distribution of the patients in respect to age and sex can be seen in table No. 1

Table 1

Age	Men	Women	Total	Percent age
5-14	10	8	18	7

55-64	3	3	6	9
Total	42	25	67	100

Examinations

All of the patients have undergone the usual oto-rhinolaryngological examination, including tone audiometry and tuning-fork tests.

Regarding special tests, it can be mentioned that qualitative impedance measurements, with efforts to register the stapedius reflex, have been performed in 50 cases. Most of the impedance measurements have been performed with an acoustical bridge, according to the

method of Metz (1946). Only a few impedance measurements were made by the cross-coupling method of Neergaard et al., (1965). In most of these cases (46) it was naturally impossible to demonstrate any stapedius reflex, as any change in the impedance resulting from a contraction of the stapedius muscle would necessitate an intact and mobile ossicular system. In a couple of cases, weak stapedius reflex reactions were detected, in spite of defects in the ossicular system (absence of the long process of the incus). During the subsequent operations, adhesions from the stapes to the handle of the malleus and the tympanic membrane were found, thus explaining these reactions. Two cases, where the cross-coupling method of impedance measurement was used, will be described to illustrate how an impedance measurement can contribute to the diagnosis of a stapes fracture.

The first patient is a 44-year-old man who, at the age of 16 years, suffered a cranial trauma with bleeding from the left ear but no loss of consciousness. From that time on, the patient had a severe loss of hearing in the left ear together with a strongly-ringing tinnitus. Audiometry indicated an air bone gap of about 50 dB. The impedance test indicated normal pressure in both middle ears. In the left ear a perceptible reflex was triggered by contra lateral stimulation, but no reflex resulted from homolateral stimulation. In the right ear only homolateral stimulation triggered the reflex. Tensor reflexes could not be detected. The examination thus suggested an interruption of the ossicular system medial to the insertion of the stapedius muscle on the head of the stapes. The operation disclosed that the stapedial arch was fractured and luxated so that the crura

rested on the promontory. The joint between the incus and the stapes was still intact, and the insertion of the tendon of the stapedius muscle was found to be normal. A small fragment of the footplate was still fastened to the anterior crus, which made possible a stable repositioning of the fractured stapedial arch. Post-operative testing revealed that the air bone gap had been reduced to 5 dB (Diagram No. 3 Case 8), and that a stapedius reflex could be demonstrated with homolateral stimulation of the left ear although it was weaker than in the right ear.

In another case the cross-coupling method demonstrated a stapedius reflex and a stronger tensor reflex in the relevant ear. The patient was a 28-year-old man who had suffered a cranial trauma 13 years before. The operation disclosed a fracture of the stapedial arch. A polyethylene tube was interposed between the long process of the incus and the stapes footplate (Diagram No. 3 Case 6).

X-ray examinations of the ear were performed in 57 cases, using the conventional projections (Schüller's, Stenver's, and the Chance III). In only a few cases did these radiographs provide information leading to a suspicion of a defective or luxated ossicle. In 41 cases, the X-ray examination was supple-

mented with tomographic examination, using the Polytome in both the frontal and sagittal planes, as a rule. There was good agreement between the radiological and the surgical disclosures in 20 cases.

Only a few individual patients were given tuba function examinations in the form of catheterization of the Eustachian tube. Many of the patients, however, had been treated with tuba catheterization or air inflation, according to Politzer's method, for varying periods prior to admission to hospital.

Surgical Evidence

Five of the patients in the post-infectious group of 28 could not give any information about previous occurrence of otitis media or any other cause of the loss of hearing, but these cases have been tabulated as post-infectious because of cicatrized tympanic membranes like those found after otitis media. In 22 cases, surgery disclosed that the lenticular process and the long process of the incus were absent to a greater or lesser degree, sometimes replaced by a fibrous cord, but that the stapes were intact. In the six remaining cases, the stapedial arch was more or less defective, and in five of these cases, it was not possible to find any trace of the incus.

In one case (an 11-year-old girl) a little cholesteatoma was found behind an intact tympanic membrane. The cholesteatoma had caused the atrophy of the long process of the incus and the crura of the stapes. There was no history of otitis media, paracentesis, or similar condition which could explain the presence of the cholesteatoma. It must therefore be considered to have been a primary cholesteatoma.

Among the 21 cases of hearing losses resulting from cranial traumata, bleeding from the ear is recorded in the journals of 18 of the patients, and in three cases leakage of cerebrospinal fluid is also recorded as having persisted for periods of varying duration. Four of these patients experienced temporary facial paralysis.

In ten cases, the incus was found to be more or less luxated and in three cases, the incus could not be located. A fracture of the handle of the malleus occurred with the incus luxation in two cases. Fractures of the stapes crura sometimes with attendant dislocation of the stapedia arch were found in eight patients. In seven of these cases, only the stapes were found to be fractured. In the remaining case, the incus was additionally found to be luxated out of the field of vision.

The 11 post-operative traumata tabulated above refer to hearing losses after mastoidectomy during childhood. The incus was found to be luxated to various degrees in five of these cases, while the incus was not observed at all in the remaining six patients.

In four cases, the hearing loss had followed traumata through the external meatus. The objects directly responsible for the traumata were a paracentesis needle, a hair clip, a twig, and a straw. The operations disclosed fractures of the stapes crura in two cases, and in the last two cases, the long process of the incus and the stapes crura had necrotized away although the head of the stapes was present in both of these cases, still fastened to the stapedius tendon. It must be assumed that the immediate injuries in both of these cases were fractures of the long process and the stapes crura resulting in an insufficient supply of blood except for the head of the stapes.

In one case—a girl of nine years—the cause of the hearing loss is tabulated as congenital. The patient was an identical twin (the other had died at birth) and had an asymmetrical face. The auricle on the side having the defective hearing was smaller than the auricle on the other side. In addition, there was a preauricular fistula. X-ray examination disclosed characteristic features of Franceschetti's Syndrome. The operation showed the incus to be deformed and without connection with the stapes. The ear was also found to be fixed in the epitympanic recess. It was mobilized, excised, and disposed between the stapes and the tympanic membrane.

One case is tabulated as having developed after radiological treatment. The patient was a boy of 14 years, who two years previously had received radiation treatment for a reticular sarcoma in the rhino-pharyngeal region. Surgery revealed the long process of the incus to have been replaced by a fibrous cord. An attempt was made to extract the remains of the incus, but the body of incus was found to be in an advanced stage of halisteresis, and crumbled away completely as the extraction was attempted.

Four patients are registered under the heading "unknown". In these cases, there are no clues suggesting otitis media, cranial traumata, or any of the other listed causes of hearing losses. Otoscopic examination showed normal tympanic membranes, and the patients explain that the hearing losses have gradually accumulated over a period of years. In two of these cases, the long process of the incus was found to have been replaced by a fibrous cord. In the other two cases, the stapes crura were found to have been replaced by a similar fibrous cord. Microscopic examination of the remnant of the stapes in one of these cases revealed a structureless area where the lacunae ossium were empty without activity of osteoblasts and osteoclasts.

Treatment and Results

The treatment in all cases has consisted of ossicular plastic surgery using a transmeatal approach to the middle ear according to Rosen's method. General anaesthesia has been used in 49 of the operations, the remainder being performed under local anaesthesia. As previously mentioned, the series consists of 71 ears, but a total of ten re-operations have been carried out, so that the results of 81 operations in all must be described.

The character of the ossicular plastic surgery to a certain extent, has been dependent upon the state of the ossicular system in each individual case.

In order to reach some judgement of the

Diagram No. 1 Series I, Group I

- A. Nos 1-4. Interposition of a bone fragment between the head of the stapes and the long process of the incus.
- B. Nos 5-8. Interposition of a polyethylene tube between the head of the stapes and the long process of the incus.
- C. No. 9. Reposition of location of the incudo-stapedial articulation.

Influence of the operational technique and the state of the ossicles on the ultimate results, it has consequently been felt desirable to separate the series into groups according to the type of defect, and its site in the ossicular system.

1 Necrosis and fracture of the lenticular process of the incus and luxation of the incudo-stapedial articulation.

2. Partial or total absence of the incus, and dislocation of the incus.

3 Necrosis or fracture of the stapedial arch.

4 Partial or total absence of the incus, combined with a defect in the stapedial arch.

As it may be seen in Diagrams Nos. 1 2 3 and 4 associated with each of these groups, the following information is tabulated for each operation.

A. Improvement or loss of hearing, expressed as the mean of the speech frequencies

500 1000 and 2000 Hz recorded during the most recent follow-up test.

B The maximum improvement in hearing, expressed as the arithmetic mean of the above mentioned speech frequencies. This is determined, as a rule, one to three months after the operation. By comparing the values of Point A and Point B the amount of hearing loss during the observation period can be determined.

C. The arithmetic mean of the pre-operative bone-conduction hearing ability at the speech frequencies 500 1000 and 2000 Hz.

1 Necrosis and fracture of the lenticular process of the incus and luxation of the incudo-stapedial articulation.

This group, consisting of nine operations (one of which was a re-operation) where reconstruction of the normal ossicular function has been attempted by 1 Interposition of

In ten cases, the incus was found to be more or less luxated, and in three cases, the incus could not be located. A fracture of the handle of the malleus occurred with the incus luxation in two cases. Fractures of the stapes crura, sometimes with attendant dislocation of the stapedia arch were found in eight patients. In seven of these cases, only the stapes were found to be fractured. In the remaining case, the incus was additionally found to be luxated out of the field of vision.

The 11 post-operative traumata tabulated above refer to hearing losses after mastoidectomy during childhood. The incus was found to be luxated to various degrees in five of these cases while the incus was not observed at all in the remaining six patients.

In four cases, the hearing loss had followed traumata through the external meatus. The objects directly responsible for the traumata were a paracentesis needle, a hair clip, a twig, and a straw. The operations disclosed fractures of the stapes crura in two cases, and in the last two cases, the long process of the incus and the stapes crura had necrotized away although the head of the stapes was present in both of these cases, still fastened to the stapedia tendon. It must be assumed that the immediate injuries in both of these cases were fractures of the long process and the stapes crura, resulting in an insufficient supply of blood except for the head of the stapes.

In one case—a girl of nine years—the cause of the hearing loss is tabulated as congenital. The patient was an identical twin (the other had died at birth) and had an asymmetrical face. The auricle on the side having the defective hearing was smaller than the auricle on the other side. In addition, there was a preauricular fistula. X-ray examination disclosed characteristic features of *Franceschetti's* Syndrome. The operation showed the incus to be deformed and without connection with the stapes. The incus was also found to be fixed in the epitympanic recess. It was mobilized, excised, and interposed between the stapes and the tympanic membrane.

One case is tabulated as having developed after radiological treatment. The patient was a boy of 14 years, who two years previously had received radiation treatment for a reticular sarcoma in the rhino-pharyngeal region. Surgery revealed the long process of the incus to have been replaced by a fibrous cord. An attempt was made to extract the remains of the incus but the body of incus was found to be in an advanced stage of haliteresis, and crumbled away completely as the extraction was attempted.

Four patients are registered under the heading "unknown." In these cases, there are no clues suggesting otitis media, cranial traumata, or any of the other listed causes of hearing losses. In the other two cases, the stapes crura were found to have been replaced by a similar fibrous cord. Microscopic examination of the remnant of the stapes in one of these cases revealed a structureless area where the lacunae ossium were empty without activity of osteoblasts and osteoclasts.

Treatment and Results

The treatment in all cases has consisted of ossicular plastic surgery using a transmeatal approach to the middle ear according to *Rosen's* method. General anaesthesia has been used in 49 of the operations, the remainder being performed under local anaesthesia. As previously mentioned, the series consists of 71 ears, but a total of ten re-operations have been carried out, so that the results of 81 operations in all must be described.

The character of the ossicular plastic surgery to a certain extent, has been dependent upon the state of the ossicular system in each individual case.

In order to reach some judgement of the

cases) or polyethylene tube (seven cases) between the head of the stapes and the tympanic membrane has also been carried out.

In one case, a polyethylene tube with a flare has been interposed between the head of the stapes and the handle of the malleus.

Myringo-stapedio-pecti has been performed in two additional cases.

The patient listed as Case 11 has been re-operated and listed again as Case 12. During the first operation, the incus was found to be significantly dislocated. The incus was then placed in contact with the stapes head, to form a columella. Upon re-operation, it was disclosed that the connection between the body of the incus and the stapes head was quite loose. This articulation was improved by creating a little excavation in the body of the incus, to accept the head of the stapes. The short process of the incus was interposed under the handle of the malleus.

One year after the operation, the flare of the polyethylene tube was observed to have partially perforated the tympanic membrane in the case listed as Case 35. In order to reduce the possibility of tympanic-membrane perforation by the polyethylene tube, the chorda tympani was placed between the prosthesis and the tympanic membrane in Case 40 and in Case 36 a little piece of bone was placed between the flared polyethylene tube and the tympanic membrane.

The results are tabulated in Diagram 2.

3 Necrosis or fracture of the stapedial arch. This group consists of eight operations, where the normal ossicular effect has been sought reconstructed, partly by the interposition of polyethylene tube between the stapes footplate and the long process of the incus (six cases), and partly by the reduction of a fractured and dislocated stapedial arch (two cases). Two of these cases have already been described (Cases 6 and 8 see page 25).

The patient tabulated as Case 4 has been re-operated. During the first operation, a polyethylene tube was positioned between the foot

Diagram No. 3. Series I, Group 3

B. Nos. 7-9. Reposition of a fractured and dislocated stapedial arch.

plate and the long process of the incus. Upon re-operation, this prosthesis was replaced by interposing the incus between the footplate and the tympanic membrane, for which reason this re-operation is included in Group 4 (Diagram 4 Case 4).

The results are tabulated in Diagram 3

4 Partial or total absence of the incus, combined with a defect in the stapedial arch. Group No. 4 consists of 20 operations (including seven re-operations). In this group, a columella effect has been sought through the interposition of bone fragments (four cases) polyethylene tube (seven cases) or the incus (six cases) between the stapes footplate and the tympanic membrane.

In Cases 7, 8, and 9 interposition was attempted using the head and neck of the malleus, supplemented by a little piece of bone. Actually these three cases are made up of one patient who has been re-operated twice. In the final re-operation (Case 9), an attempt was

pieces of bone or polyethylene tube traversing the defect from the head of the stapes to the long process of the incus (eight cases) 2 Repositioning of a luxation of the incudo-stapedial articulation (one case)

The results obtained are tabulated in Diagram No. 1 where Case 4 is the result of the re-operation of Case 7. In the first operation, a polyethylene tube was interposed between the head of the stapes and the long process of the incus. Upon re-operation, the polyethylene tube was found to have slipped off the long process of the incus so that it contacted the tympanic membrane, where there was a little perforation. The patient was then re-operated, and a little piece of bone interposed in the defect, but this didn't result in any improvement in hearing, and the patient has since been re-operated twice (Diagram 4 Cases 5 and 6) During the re-operation of Case 8 (Diagram No. 1) it was observed that the poly

ethylene tube interposed between the head of the stapes and the long process of the incus had produced additional necrosis of the latter ossicle. The polyethylene tube was consequently removed and the body of the incus itself was interposed between the head of the stapes and the tympanic membrane, with a good improvement in hearing as a result (Diagram No. 2 Case 27)

2 Partial or total absence of the incus, and dislocation of the incus.

In this group of 44 operations (including two re-operations) attempts have been made to achieve a columella effect in 30 cases by interposing the body of the incus between the head of the stapes, the handle of the malleus, and the tympanic membrane. No special effort has been made to secure contact between the incus and the handle of the malleus.

The interposition of bone fragments (four

Table 3

	Quantity	Arithmetic mean increase in hearing	Number of cases at or above specified level		Post-operative air-bone gap		
		dB	20 dB level	30 dB level	10 dB or less	15 dB	20 dB
Group No. 1 Defective lenticular process, luxation of the pseudo-stapedial joint	9	5 (12)	1	6	2	3	3
Group No. 2 Partial or complete absence of the incus, luxation of the incus	44	18 (22)	15	30	18	27	35
Interposition of the incus between the head of the stapes and the tympanic membrane	30	13 (19)	8	18	12	18	23
Group No. 3 Necrosis or fracture of the stapedial arch	8	14 (24)	3	6	3	6	6
Group No. 4 Partial or complete absence of the incus combined with defective stapedial arch	20	4 (11)	1	6	3	7	8

The mean improvement in hearing for the entire Series I amounted to 13 dB.

In the speech-frequency spectrum, hearing was improved by 10 dB or more in 51 cases, i.e. approx. 63 per cent. In 10 cases, there was a hearing loss of 10 dB or more, i.e. approx. 12 per cent.

The improvement in hearing culminates, as a rule, from one to three months after the operation, after which time hearing losses of 10 dB or more occurred in 24 cases (30 per cent).

The following data for each group will be found in Table 3.

1. The average improvement in hearing.
2. The number of cases where the post operative threshold of hearing is 20 dB, 30 dB, or better.
3. The number of cases where the post operative air-bone gap is 10 dB, 15 dB, 20 dB, or less.

The arithmetic mean average improvement in hearing in Group No. 3 is only eight dB when Case 7 (where the normal ossicular system was re-established) is not included. Such a re-establishment of a normally-functioning ossicular system must be considered to be an extreme rarity.

The values given in parentheses in the column of mean average improvement of hearing provide the mean value of the maximum improvement measured during the observation period, which is from one month to six years after the operation.

The number of cases observed for six months, one year, two years, or longer can be ascertained by consulting the diagrams.

A comparison of the results obtained through reconstruction of the transmission mechanism using bone fragments, remains of ossicles, or polyethylene tube will be found in Table 4.

It may readily be seen that polyethylene tube

Diagram No 4 Series I Group A

- A. Nos. 1-6. Interposition of the incus between the stapes footplate and the tympanic membrane.
- B. Nos. 7-9. Interposition of the head of the malleus between the stapes footplate and the tympanic membrane (in Cases 8 and 9 supplemented by a little piece of bone)
- C. Nos. 10-13. Interposition of a bone fragment between the stapes footplate and the tympanic membrane.
- D. Nos. 14-20. Interposition of a polyethylene tube between the stapes footplate and the tympanic membrane

made to improve the position of the interposed pieces of bone, but the patient's hearing subsequently deteriorated again.

In six cases where the lenticular process or the long process is missing the incus has been interposed between the footplate and the tympanic membrane (with the short process or the long process resting on the footplate and with the body of the incus contacting the tympanic membrane). No special effort has been made to secure contact with the handle of the malleus, or to place the body of the incus under the handle of the malleus.

Cases 5 and 6 are the second and the third re-operation of Case 7 in Group No. 1. The original operation and first re-operation have

already been discussed. During the second and third re-operations, the stapedial arch was found to be completely necrotized, which is the reason for their inclusion in Group No. 4. Under the second re-operation, the incus was interposed between the footplate and the tympanic membrane. There was an immediate improvement in hearing (15 dB) but after period of three years, the final result was 15 dB loss of hearing. The third re-operation disclosed that the incus was fixed to the reticuli by a fibrous band, but loosening of the band produced no improvement in hearing function.

The patient listed as Case 18 has been re-operated twice. A polyethylene tube was introduced between the footplate and the tympanic membrane during the original operation. It was discovered during the first re-operation (Case 19) that the polyethylene prosthesis had disappeared (perforated through the tympanic membrane?). Another polyethylene tube was therefore introduced, bridging from the footplate to the tympanic membrane. During the second re-operation (Case 13) the polyethylene tube was found to be somewhat dislocated. An effort was then made to introduce a piece of bone between the footplate and the tympanic membrane but the footplate was injured during this operation, resulting in a 10 dB loss of hearing.

Case 20 likewise represents a re-operated patient. During the original operation, a polyethylene tube was interposed between the footplate and the tympanic membrane. The patient was thereafter periodically disturbed by attacks of a feeling of instability especially when changing the attitude of the head, and a slight hearing loss of 10 dB developed. Re-operation disclosed that the polyethylene tube had caused a perforation of the footplate. The oval window was then covered with a piece of vein, and the polyethylene tube interposed between the bit of vein and the tympanic membrane. This re-operation is not included in Series I.

The results of this group are tabulated in Diagram No. 4.

Table 3

	Quantity	Arithmetic mean increase in hearing dB	Number of cases at or above specified level		Post-operative air-bone gap		
			20 dB level	30 dB level	10 dB or less	15 dB	20 dB

- B. Nos. 7-9. Interposition of the head of the malleus between the stapes footplate and the tympanic membrane (in Cases 8 and 9 supplemented by a little piece of bone).
- C. Nos. 10-13. Interposition of a bone fragment between the stapes footplate and the tympanic membrane
- D. Nos. 14-20. Interposition of a polyethylene tube between the stapes footplate and the tympanic membrane

made to improve the position of the interposed pieces of bone, but the patient's hearing subsequently deteriorated again.

In six cases where the lenticular process or the long process is missing, the incus has been interposed between the footplate and the tympanic membrane (with the short process or the long process resting on the footplate, and with the body of the incus contacting the tympanic membrane). No special effort has been made to secure contact with the handle of the malleus, or to place the body of the incus under the handle of the malleus.

Cases 5 and 6 are the second and the third re-operation of Case 7 in Group No. 1. The original operation and first re-operation have

already been discussed. During the second and third re-operations, the stapedial arch was found to be completely necrotized, which is the reason for their inclusion in Group No. 4. Under the second re-operation, the incus was interposed between the footplate and the tympanic membrane. There was an immediate improvement in hearing (15 dB) but after a period of three years, the final result was a 15 dB loss of hearing. The third re-operation disclosed that the incus was fixed to the rear wall by a fibrous band, but loosening of this band produced no improvement in hearing function.

The patient listed as Case 18 has been re-operated twice. A polyethylene tube was introduced between the footplate and the tympanic membrane during the original operation. It was discovered during the first re-operation (Case 19) that the polyethylene prosthesis had disappeared (perforated through the tympanic membrane?). Another polyethylene tube was therefore introduced bridging from the footplate to the tympanic membrane. During the second re-operation (Case 13) the polyethylene tube was found to be somewhat dislocated. An effort was then made to introduce a piece of bone between the footplate and the tympanic membrane but the footplate was injured during this operation, resulting in a 10 dB loss of hearing.

Case 20 likewise represents a re-operated patient. During the original operation, a polyethylene tube was interposed between the footplate and the tympanic membrane. The patient was thereafter periodically disturbed by attacks of a feeling of instability especially when changing the attitude of the head and a slight hearing loss of 10 dB developed. Re-operation disclosed that the polyethylene tube had caused a perforation of the footplate. The oval window was then covered with a piece of vein, and the polyethylene tube interposed between the bit of vein and the tympanic membrane. This re-operation is not included in Series I.

The results of this group are tabulated in Diagram No. 4.

CLINICAL REPORT II

As the reader will have noted from the contents of the concluding paragraphs of the preceding material, the results of ossicular plastic surgery are not completely satisfactory.

In order to examine some of the purely mechanical aspects of the deciding factors in making successful reconstructions of defective ossicular systems, B. S. Elpern (1965-1966, 1966) and the author have performed a series of sound-transmission experiments on dissected temporal bones, where reconstructive surgery on the auditory ossicles was simulated. Among the relationships revealed were: 1. Optimal transmission of sound occurred with the use of a prosthesis which fitted precisely so as to make good and stable contact with the remainder of the ossicular system, 2. Connection of the prosthesis to the handle of the malleus provided better conduction of the high frequencies, 3. Even though the head of the malleus was missing, a prosthetic connection of the handle of the malleus to the stapes provided optimal transmission of sound in the frequency spectrum used during these experiments, i.e. up to 4000 Hz, 4. Increased tension in the transmission system (i.e. those changes brought about by certain displacements of the ossicles) resulted in low-frequency transmission losses, 5. The distance from the head of the stapes to the handle of the malleus or the tympanic membrane varies considerably from one specimen to another. Consequently the body of the incus, which has relatively constant dimensions, is not always suitable for interposition between the stapes head and the handle of the tympanic membrane, if the conditions of Point 1 above are to be met.

It now becomes possible to ask the following question: Is it possible to improve the results of ossicular plastic surgery (as judged by tone

audiograms) firstly when the above-mentioned mechanical principles are observed, and secondly when the clinical experience as expressed in the concluding paragraphs on page 32 is used?

In order to reply to these questions, the author has performed a number of operations on patients with defective ossicular system, where the above mentioned observations have been sought used to best advantage.

This patient group consists of 55 persons, three of whom were operated in both ears, so that this second series contains the results of operations on 58 ears, and Series II is thus of the same numerical order as Series I. As was the case in Series I, all of the patients in Series II had intact tympanic membranes, although these were often everted, and the middle ear was air-filled in all cases.

Two patients have been excluded from the series. In both of these cases, large perforations of the tympanic membranes occurred post-operatively and these perforations would have significantly influenced the post-operative hearing of the patients. In one of these cases, the cause of perforation was a post-operative infection. The other patient had been radiologically treated for a *reticulo-sarcoma* in the rhinopharynx, and thereafter developed a loss of hearing because of a radiation-induced defect in the ossicular system (fibrous degeneration of the long process of the incus). Post-operatively a perforation of the entire posterior portion of the pars tensa slowly developed (perhaps due to reduced vitality caused by the radiation?).

Statistical material in Series II has been treated in the same manner as in the preceding Series I.

The patient group is distributed according to age and sex as can be seen in Table 5

Table 4

	Quantity	Arithmetic mean im- provement in hearing dB	Number of cases at or above specified level		Post-operative air-bone gap		
			70 dB level	30 dB level	10 dB	15 dB	70 dB
1 Ossicular Remains	41	13	11	5	18	26	3
2 Bone Fragments	1	16	4	9	4	5	7
3 Polyethylene Tube	5	9	4	11	4	9	10

has produced worse results than either ossicular remains or bone fragments. In a couple of cases (Diagram 2, Cases 32 and 33) good improvements in hearing lasting more than four years have been achieved using bone prostheses.

Complications

As previously mentioned in one case re-operation disclosed that the stapes footplate was ulcerated through the agency of the polyethylene tube prosthesis (Diagram 4 Case 20). This caused a slight loss of hearing of about 10 dB (which was measured as a drop in the bone-conduction threshold ranging from five to 20 dB). However a quite distressing dizziness following changes in attitude resulted from this injury.

In another case (Diagram 4 Case 18) the stapes footplate was injured during the second re-operation (Case 13) which only resulted in a slight loss of hearing of about 10 dB (measurement of bone-conduction threshold indicated reductions of from 25 to 40 dB). There have been no cases with a total loss of the cochlear function.

Three patients have post-operatively complained of slight disturbances of the taste sense.

Infection of the middle ear has been observed post-operatively in two cases, but the infection was quickly cleared up with the use of antibiotics. More serious infections, such as labyrinthitis or meningitis, have not been observed nor have there been any cases of facial paralysis.

Conclusions

The relatively limited size of this clinical series, and the resultant uncertainty of the data thus collected must be taken into consideration when attempting to draw conclusions from this material.

Essentially however the results seem to be in agreement with what would be expected after study of the literature.

1 Polyethylene tube must be considered to be an unsuitable material for the reconstruction of the sound transmission mechanism in most cases.

2 Pieces of bone and the remains of ossicles are quite suitable, and can produce satisfactory results of longer duration, but in 26 per cent of these cases, the initial improvement in hearing was found to deteriorate by at least 10 dB after an interval of from one to three months.

3 The average improvement in hearing are greatest when the stapes is intact. This, however is not valid for the group with a defective lenticular process of the malleus or a luxation of the incudo-stapedial articulation. In these cases, the improvement in hearing is astonishingly poor but it should be noted that this group consists of only nine patients.

4 Even in cases where the stapes is intact the hearing improvements obtained are extremely variable, and do not bear comparison with the results obtained with modern otosclerosis surgery (Andersen and Warrer 1966).

cases replaced by fibrous cords. In the remaining 16 cases, the stapedial arch was also more or less defective.

A case of cholesteatoma behind an intact tympanic membrane was found in this series as well. Like the case in Series I, this patient could not provide any anamnesis of otitis media, pericentesis, etc., for which reason this case must likewise be considered to be a primary cholesteatoma. The operation disclosed that the cholesteatoma had caused the destruction of the long process of the incus, but the head of the malleus was also found to be fixed to the wall of the atticus.

In 11 of the 13 cranial traumatic cases causing loss of hearing, there are reports of bleeding, and in at least two of these cases, leakage of cerebro-spinal fluid was also reported. In one of these later cases, cerebral matter was found in the external meatus. Three patients had experienced temporary facial paralysis. These figures with the corresponding figures in Series I naturally are no indication of the frequency of ossicle luxation in patients having displayed aurial haemorrhage after cranial trauma, but they emphasize the importance of examining such patients both otologically and radiologically.

In eight cases, the incus was found to be luxated, and in three of these cases, it was luxated completely out of the field of the operation, and could not be found. In two cases, the handle of the malleus was found to be fractured, in addition to the luxation of the incudo-stapedial articulation. In another case a luxation of both incus and malleus was found combined with a fixation of the malleus in the epytympanic recess. In one case, an incus luxation was found combined with a fracture of the stapes crura. In the remaining case, an isolated fracture of the stapes crura was observed.

In eight other cases, the loss of hearing occurred after mastoidectomy. In six of these cases, there was no trace of the incus. In one case, the malleus was also missing, but in spite of this, the patient's tympanic membrane was

intact. In the last two cases, the incus was found to be rather severely dislocated.

In one case, loss of hearing occurred after a trauma caused by a foreign body (a twig) inserted through the external meatus. The operation disclosed a luxation of the incudo-stapedial articulation.

Two cases have been tabulated under the heading Aetiology Unknown. In these cases, the hearing loss occurred gradually and the tympanic membranes were normal. The operation disclosed that the long process of the incus was defective in both cases.

As was expected, the features disclosed by surgery in both Series I and Series II indicate that ossicular defects are most often centered on the incus, while the stapedial arch is also frequently defective as well. It is noteworthy that in both series, isolated fracture and luxation of the stapes crura has been observed a total of ten times. It should also be noted that in four cases, a fracture of the handle of the malleus has been confirmed in addition to luxation of the incus. In two cases, a luxation of the malleus has also been observed.

Perusal of Diagrams I to II suggests that the pre-operative air-bone gap in Series II has varied from 15 to 65 dB. It has previously been stated that an ossicular defect with intact tympanic membrane should produce a loss of hearing of approximately 50 to 60 dB (page 1), but that hearing losses of less severity than expected might be due to fibrous cords or bands from the stapes (e.g. from the stapes footplate) to the long process of the incus, the handle of the malleus, or the tympanic membrane.

Series II contained a group of 37 cases where a pre-operative air-bone gap of from 15 to 40 dB was measured, and in 28 of these cases, the above-mentioned fibrous connections were found. However there were nine cases with such fibrous connections among a group of 21 patients whose air-bone gaps were in the range of 40 to 50 dB.

These figures do support the assumption, though, that the fibrous bands and cords are

Table 5

Age	Men	Women	Total	Percentage

15-24	8	8	16	29
25-34	6	4	10	18
35-44	5	3	8	15
45-54	5	5	10	18
55-64	4	2	6	11
Total	3	23	35	100

Examinations

The patients have been examined according to the same principles and procedures as for Series I.

It should be noted that emphasis has been placed on negative results of Rinne's Tuning fork Test in both Series I and Series II. This implies that the ear in question has an air bone gap of at least 15 dB.

Impedance tests have been performed in 37 cases. In 27 of these the cross-coupling method was used (Neergaard et al. 1965). In five cases, stapedius reflex reactions of various strengths were detected. Operations on these patients revealed fibrous cords or bands from the stapes to the tympanic membrane, the handle of the malleus or the long process of the incus, explaining the impedance changes due to the stapedius reflex. In four ears, stronger tactile tensor reflex reactions than in the corresponding (normal) ear were detected. This can be interpreted, as previously mentioned, as the effect of a greater looseness of the malleus, due to the defect in the ossicular system. In this series the pressure in the middle ear was also measured in 27 cases (Terkildsen 1962). In 17 cases, the pressure in the middle ear was found to be normal which has been interpreted as indicating that the Eustachian tube functioned normally. In three cases, the middle-ear pressure could not be determined. This was found in one case, to be due to a little cholesteatoma behind the tympanic membrane. In seven cases, a slightly negative pressure was measured (ranging from -6 cm to -12 cm of water) but in spite of this it has been possible

Table 6 *Distribution According to Aetiology*

	Total	Men	Women

Unknown	2		
Total	58	33	25

to achieve satisfactory and apparently lasting improvements in the hearing function. With the exception of the middle-ear pressure measurements, no examinations of function of the Eustachian tube have been made in Series II.

Tomographic X-ray examinations in the frontal and sagittal planes have been performed in 50 cases, and in 29 cases there was good agreement between the tomographic and operative observations. In Series I the corresponding figures were 41 and 20 which indicates that the tomographic X-ray examination with the Polytome has been of greater diagnostic value in Series II than in Series I. It should be noted that the tomographic examination seems, to an increasing degree, to be able to provide a diagnosis even in cases of less obvious defects in the ossicles, such as a defective long process of the incus.

Surgical Evidence

Five of the 33 patients in the post-infectious group were unable to provide any information about previous occurrence of otitis media or any other reason for their hearing loss. However, due to the fact that the tympanic membrane in each case was cicatrized, they have been included in that group. In 17 cases, the operation disclosed that the lenticular process and the long process of the incus were defective to a greater or lesser degree, and in some

replaced by fibrous cords. In the remaining 16 cases, the stapedial arch was also more or less defective.

A case of cholesteatoma behind an intact tympanic membrane was found in this series as well. Like the case in Series I, this patient could not provide any examination of otitis media, paracentesis, etc., for which reason this case must likewise be considered to be a primary cholesteatoma. The operation disclosed that the cholesteatoma had caused the destruction of the long process of the incus, but the head of the malleus was also found to be fixed to the wall of the atticus.

In 11 of the 13 cranial traumatic cases causing loss of hearing, there are reports of bleeding, and in at least two of these cases, leakage of cerebro-spinal fluid was also reported. In one of these later cases, cerebral matter was found in the external meatus. Three patients had experienced temporary facial paralysis. These figures with the corresponding figures in Series I naturally are no indication of the frequency of ossicle luxation in patients having displayed aurial haemorrhage after cranial trauma, but they emphasize the importance of examining such patients both otologically and radiologically.

In eight cases, the incus was found to be luxated, and in three of these cases, it was luxated completely out of the field of the operation, and could not be found. In two cases, the handle of the malleus was found to be fractured, in addition to the luxation of the incudo-stapedial articulation. In another case a luxation of both incus and malleus was found combined with a fixation of the malleus in the epitympanic recess. In one case, an incus luxation was found combined with a fracture of the stapes crura. In the remaining case, an isolated fracture of the stapes crura was observed.

In eight other cases, the loss of hearing occurred after mastoidectomy. In six of these cases, there was no trace of the incus. In one case, the malleus was also missing, but in spite of this, the patient's tympanic membrane was

intact. In the last two cases, the incus was found to be rather severely dislocated.

In one case, loss of hearing occurred after a trauma caused by a foreign body (a twig) inserted through the external meatus. The operation disclosed a luxation of the incudo-stapedial articulation.

Two cases have been tabulated under the heading Aetiology Unknown. In these cases, the hearing loss occurred gradually and the tympanic membranes were normal. The operation disclosed that the long process of the incus was defective in both cases.

As was expected, the features disclosed by surgery in both Series I and Series II indicate that ossicular defects are most often centered on the incus, while the stapedial arch is also frequently defective as well. It is noteworthy that in both series, isolated fracture and luxation of the stapes crura has been observed a total of ten times. It should also be noted that in four cases, a fracture of the handle of the malleus has been confirmed in addition to luxation of the incus. In two cases, a luxation of the malleus has also been observed.

Perusal of Diagrams 1 to 6 suggests that the pre-operative air-bone gap in Series II has varied from 15 to 65 dB. It has previously been stated that an ossicular defect with intact tympanic membrane should produce a loss of hearing of approximately 50 to 60 dB (page 12) but that hearing losses of less severity than expected might be due to fibrous cords or bands from the stapes (e.g. from the stapes footplate) to the long process of the incus, the handle of the malleus, or the tympanic membrane.

Series II contained a group of 37 cases where a pre-operative air-bone gap of from 15 to 40 dB was measured, and in 28 of these cases, the above-mentioned fibrous connections were found. However there were nine cases with such fibrous connections among a group of 21 patients whose air-bone gaps were in the range of 40 to 50 dB.

These figures do support the assumption, though, that the fibrous bands and cords are

Examinations

The patients have been examined according to the same principles and procedures as for Series I.

It should be noted that emphasis has been placed on negative results of Rinne's Tuning fork Test in both Series I and Series II. This implies that the ear in question has an air bone gap of at least 15 dB.

Impedance tests have been performed in 37 cases in 27 of these the cross-coupling method was used (Neergaard et al., 1965). In five cases, stapedius reflex reactions of various strengths were detected. Operations on these patients revealed fibrous cords or bands from the stapes to the tympanic membrane, the handle of the malleus or the long process of the incus, explaining the impedance changes due to the stapedius reflex. In four ears, stronger tactile tensor reflex reactions than in the corresponding (normal) ear were detected. This can be interpreted as previously mentioned, as the effect of a greater looseness of the malleus, due to the defect in the ossicular system. In this series, the pressure in the middle ear was also measured in 27 cases (Terklidsen, 1962). In 17 cases, the pressure in the middle ear was found to be normal, which has been interpreted as indicating that the Eustachian tube functioned normally. In three cases, the middle-ear pressure could not be determined. This was found, in one case to be due to a little cholesteatoma behind the tympanic membrane. In seven cases, a slightly negative pressure was measured (ranging from -6 cm to -12 cm of water) but in spite of this it has been possible

to achieve satisfactory and apparently lasting improvements in the hearing function. With the exception of the middle-ear pressure measurements, no examinations of function of the Eustachian tube have been made in Series II.

Tomographic X ray examinations in the frontal and sagittal planes have been performed in 50 cases, and in 29 cases there was good agreement between the tomographic and operative observations. In Series I the corresponding figures were 41 and 20 which indicates that the tomographic X ray examination with the Polytome has been of greater diagnostic value in Series II than in Series I. It should be noted that the tomographic examination seems, to an increasing degree, to be able to provide a diagnosis even in cases of less obvious defects in the ossicles, such as a defective long process of the incus.

Surgical Evidence

Five of the 33 patients in the post-infectious group were unable to provide any information about previous occurrence of otitis media or any other reason for their hearing loss. However, due to the fact that the tympanic membrane in each case was cicatrized they have been included in that group. In 17 cases the operation disclosed that the lenticular process and the long process of the incus were defective to a greater or lesser degree and in some

cases replaced by fibrous cords. In the remaining 16 cases, the stapedia arch was also more or less defective.

A case of cholesteatoma behind an intact tympanic membrane was found in this series as well. Like the case in Series I, this patient could not provide any anamnesis of otitis media, paracentesis, etc. for which reason this case must likewise be considered to be a primary cholesteatoma. The operation disclosed that the cholesteatoma had caused the destruction of the long process of the incus, but the head of the malleus was also found to be fixed to the wall of the striae.

In 11 of the 13 cranial traumatic cases causing loss of hearing, there are reports of bleeding, and in at least two of these cases, leakage of cerebro-spinal fluid was also reported. In one of these later cases, cerebral matter was found in the external meatus. Three patients had experienced temporary facial paralysis. These figures with the corresponding figures in Series I naturally are no indication of the frequency of ossicle luxation in patients having displayed aurial haemorrhage after cranial trauma, but they emphasize the importance of examining such patients both otologically and audiologically.

In eight cases, the incus was found to be luxated, and in three of these cases, it was luxated completely out of the field of the operation, and could not be found. In two cases, the handle of the malleus was found to be fractured, in addition to the luxation of the incudo-stapedial articulation. In another case a luxation of both incus and malleus was found combined with a fixation of the malleus in the epitympanic recess. In one case, an incus luxation was found combined with a fracture of the stapes crura. In the remaining case, an isolated fracture of the stapes crura was observed.

In eight other cases, the loss of hearing occurred after mastoidectomy. In six of these cases, there was no trace of the incus. In one case, the malleus was also missing, but in spite of this, the patient's tympanic membrane was

intact. In the last two cases, the incus was found to be rather severely dislocated.

In one case, loss of hearing occurred after a trauma caused by a foreign body (a twig) inserted through the external meatus. The operation disclosed a luxation of the incudo-stapedial articulation.

Two cases have been tabulated under the heading Aetiology Unknown. In these cases, the hearing loss occurred gradually and the tympanic membranes were normal. The operation disclosed that the long process of the incus was defective in both cases.

As was expected, the features disclosed by surgery in both Series I and Series II indicate that ossicular defects are most often centered on the incus, while the stapedia arch is also frequently defective as well. It is noteworthy that in both series, isolated fracture and luxation of the stapes crura has been observed a total of ten times. It should also be noted that in four cases, a fracture of the handle of the malleus has been confirmed in addition to luxation of the incus. In two cases, a luxation of the malleus has also been observed.

Perusal of Diagrams 1 to 6 suggests that the pre-operative air-bone gap in Series II has varied from 15 to 65 dB. It has previously been stated that an ossicular defect with intact tympanic membrane should produce a loss of hearing of approximately 50 to 60 dB (page 12) but that hearing losses of less severity than expected might be due to fibrous cords or bands from the stapes (e. g. from the stapes footplate) to the long process of the incus, the handle of the malleus, or the tympanic membrane.

Series II contained a group of 37 cases where a pre-operative air-bone gap of from 15 to 40 dB was measured, and in 28 of these cases, the above-mentioned fibrous connections were found. However there were nine cases with such fibrous connections among a group of 21 patients whose air-bone gaps were in the range of 40 to 50 dB.

These figures do support the assumption, though, that the fibrous bands and cords are

Examinations

The patients have been examined according to the same principles and procedures as for Series I.

It should be noted that emphasis has been placed on negative results of Rinne's Tuning fork Test in both Series I and Series II. This implies that the ear in question has an air bone gap of at least 15 dB.

Impedance tests have been performed in 37 cases in 27 of these the cross-coupling method was used (Neergaard et al. 1965). In five cases, stapedius reflex reactions of various strengths were detected. Operations on these patients revealed fibrous cords or bands from the stapes to the tympanic membrane, the handle of the malleus or the long process of the incus explaining the impedance changes due to the stapedius reflex. In four ears, stronger tactile tensor reflex reactions than in the corresponding (normal) ear were detected. This can be interpreted as previously mentioned as the effect of a greater looseness of the malleus, due to the defect in the ossicular system. In this series, the pressure in the middle ear was also measured in 27 cases (Terkiltsen, 1962). In 17 cases, the pressure in the middle ear was found to be normal, which has been interpreted as indicating that the Eustachian tube functioned normally. In three cases, the middle-ear pressure could not be determined. This was found in one case, to be due to a little cholesteatoma behind the tympanic membrane. In seven cases, a slightly negative pressure was measured (ranging from -6 cm to -12 cm of water) but in spite of this it has been possible

fix of the handle of the malleus ventrally in the tympanic cavity

It can be seen that the bone prosthesis has excursions which serve to ensure a good and stable contact with the head of the stapes and the handle of the malleus, and in addition, there is a slightly curved surface where the prosthesis will contact the tympanic membrane, which contributes to stability when the tympanic membrane is returned to its correct position at the conclusion of the operation. The thickness of the bone is about 2 mm. In the greatest majority of cases, the bone prosthesis has been cut out of the cortex of the lateral surface of the mastoid process. In three cases only has the body of the incus provided the material for the prosthesis.

Using bone prostheses of the type described, it has occasionally been possible to obtain a convincing improvement in hearing very quickly after the operation, as may be seen by study of Figure 2, which shows the hearing improvement obtained three days after the operation (Diagram 5 Case 12)

Due to the fact that this is too early for fibrous adhesion processes to have taken place, this effect must indicate that the bone prosthesis works satisfactorily in the purely mechanical

sense. The installation of these bone prostheses has had the primary aim of creating a columella effect, but it is possible that the handle and the prosthesis develop a certain leverage effect as well.

The results are tabulated in Diagram 5

Cases 26 28 and 33 are re-operations of Cases 25 27 and 32 respectively. The re-operations of Cases 26 and 28 disclosed that there was poor contact with the stapes. New prostheses which fitted better were formed, and a good improvement in hearing was achieved in these two cases. Re-operation of Case 33 did not provide any clear explanation of the reason for the lack of improvement in hearing.

After the operation of Case 31 a conductive hearing loss of 30 dB has resulted. Tomography has shown that the bone prosthesis has slipped out of position, but this patient has not yet been re-operated.

In Case 40 both the incus and malleus were missing (after mastoidectomy in childhood), while the stapes was intact and mobile. As can be seen, a bone prosthesis interposed between the stapes and the intact tympanic membrane produced an exceptional improvement in the patient's hearing.

In Case 41 luxations of both the incus and

able to transmit a certain amount of sound through the middle ear. But it must be noted that the pre-operative air bone gap in some cases, can apparently be less than expected because of a scarred or perhaps partially atrophied tympanic membrane.

Treatment and Results

Series II as previously mentioned, consists of 58 ears where, due to five re-operations, a total of 63 ossicular plastic operations have been performed. A transmastal approach according to Rosen's method has been used in all of the operations. Nine operations were performed under local anaesthesia, while the remainder were done under a general anaesthesia. It must be considered an advantage to use a local anaesthesia for ossicular plastic surgery as the patient's remarks relating to a subjective improvement in hearing can be a significant aid in correctly positioning the prosthesis.

The character of the ossicular plastic surgery included in this series has depended upon whether or not the stapes has been intact or not. Series II can therefore be divided into two groups:

- 1 The 42 cases where the stapes was intact
2. The 21 cases where the stapedial arch was absent, while the stapes footplate was normal.

For each operation, as was the case in Series I the following information can be seen in Diagrams 5 and 6.

A. Hearing improvement or loss expressed as the arithmetic mean of the speech frequencies 500 1000 and 2000 Hz, measured during the most recent follow-up examination

B The maximum improvement in the mean average of the above-mentioned frequencies. This maximum is often observed from one to three months after the operation. By comparing the values of Point A and B the hearing loss occurring during the observation period can be ascertained.

C. Pre-operative bone-conduction as the mean of the speech frequencies 500 1000 and 2000 Hz.

1 Intact stapes

This group consists of 42 operations (including two re-operations). In all cases the prosthesis consists of a shaped piece of bone interposed between the head of the stapes and the handle of the malleus and the tympanic membrane. The shape of the bone fragment was determined by the principles which have experimentally displayed (Elbrond and Elperin, 1966) the optimal sound transmission in the middle ear. Consequently the object has been to shape the bone prosthesis so as to fit precisely between the head of the stapes, and the handle of the malleus and the tympanic membrane, ensuring that there is good contact with the stapes head and the handle. In each individual case, the size of the bone fragment is determined by the distance from the stapes head to the handle, measured along a perpendicular to the handle (Fig. 1). It is possible to measure this dimension with relatively great accuracy (0.1 mm). In this series of operations, this dimension has varied from about 1.0 mm to approximately 2.2 mm. In one case, however the distance was 2.6 mm, but this was due to a slight luxa-

tion of the handle of the malleus ventrally in the tympanic cavity.

It can be seen that the bone prosthesis has excavations which serve to ensure a good and stable contact with the head of the stapes and the handle of the malleus, and in addition, there is a slightly curved surface where the prosthesis will contact the tympanic membrane, which contributes to stability when the tympanic membrane is returned to its correct position at the conclusion of the operation. The thickness of the bone is about 2 mm. In the greatest majority of cases, the bone prosthesis has been cut out of the cortex of the lateral surface of the mastoid process. In three cases only has the body of the incus provided the material for the prosthesis.

Using bone prostheses of the type described, it has occasionally been possible to obtain a convincing improvement in hearing very quickly after the operation, as may be seen by study of Figure 2, which shows the hearing improvement obtained three days after the operation (Diagram 5 Case 12).

Due to the fact that this is too early for fibrous adhesion processes to have taken place, this effect must indicate that the bone prosthesis works satisfactorily in the purely mechanical

sense. The installation of these bone prostheses has had the primary aim of creating a columella effect, but it is possible that the handle and the prosthesis develop a certain leverage effect as well.

The results are tabulated in Diagram 5.

Cases 26, 28, and 33 are re-operations of Cases 25, 27, and 32 respectively. The re-operations of Cases 26 and 28 disclosed that there was poor contact with the stapes. New prostheses which fitted better were formed, and a good improvement in hearing was achieved in these two cases. Re-operation of Case 33 did not provide any clear explanation of the reason for the lack of improvement in hearing.

After the operation of Case 31 a conductive hearing loss of 30 dB has resulted. Tomography has shown that the bone prosthesis has slipped out of position, but this patient has not yet been re-operated.

In Case 40 both the incus and malleus were missing (after mastoidectomy in childhood), while the stapes was intact and mobile. As can be seen, a bone prosthesis interposed between the stapes and the intact tympanic membrane produced an exceptional improvement in the patient's hearing.

In Case 41 luxations of both the incus and

db

Diagram No. 5 Series II Group I

Nos. 1-4... Interposition of a shaped piece of bone between the head of the stapes, the handle of the malleus and the tympanic membrane.

the malleus were found, as the result of a cranial trauma. The stapes was intact and mobile. The head of the malleus was found to be tightly wedged in the anterior part of the attic, for which reason the neck of the malleus was severed. The handle of the malleus was then free to move and the head of the malleus and the incus were removed.

A little cholesteatoma was disclosed in Case 42 and it was found to have caused the destruction of the distal part of the long process of the incus. In addition the head of the malleus was fixed in the attic, while the stapes was intact and mobile. As in the preceding case, the neck of the malleus was severed so that the head of the malleus and the incus could then be extracted. In both Cases 41 and 42, shaped pieces of bone were interposed between the stapes and the handle and the tympanic membrane. Good improvement in hearing is seen to have been obtained in both cases, in spite of the lack of the head of the malleus, which is in agreement with the results of experimental research (Elpern and Elbrønd 1966).

2 Defective stapedia arch

This group consists of 21 operations (including two re-operations). In 13 operations, the incus has been interposed between the stapes foot plate and the handle of the malleus. As it was reported on page 20 the distance from the footplate to the handle corresponds quite precisely in many cases to the distance from the apex of the short process of the incus to the middle of the saddle shaped articular surface on the body of the incus. The incus has consequently been interposed in these cases, with the handle resting in the middle of the saddle-shaped articulation surface. The remainder of the long process of the incus was first excised, to prevent interference with the promontory. Experimentally the interposition of the incus in this manner has produced optimal transmission of sound in temporal-bone preparations (Elbrønd and Elpern, 1966).

In two cases (Cases 10 and 12 in Diagram 6) the short process of the incus was found to be too long, and a bit of the apex of the short process was then removed. It then became

possible to place the incus in position between the footplate and the handle. Elsewhere, in Case 2, the incus was found to be a bit too short, and consequently a little piece of cartilage (from the tragus) was placed between the articulation surface on the body of the incus and the handle, in order to provide sufficient contact.

In Case 14 where the incus was found to be partially destroyed, a shaped piece of bone was interposed between the stapes footplate and the handle and the tympanic membrane. This bone prosthesis was provided with a depression, excavated as in the bone prostheses of the preceding group, fitting the manubrium of the preceding group, fitting the manubrium and having a curved contact surface facing the tympanic membrane, and with a projection resting on the footplate.

Teflon prostheses shaped to fit each individual application were used in six cases, as this procedure had also been experimentally shown to give optimal sound transmission when tested in temporal-bone preparations (Elbrønd and Elpers, 1966) interposed between the footplate and the malleus, with a clasp fitting around the handle of the malleus.

Case 20 is a re-operation of Case 19. During the first operation, a teflon prosthesis was interposed between the stapes footplate and the handle of the malleus. This resulted in an exceptional improvement in hearing, but after approximately one month, a sudden loss of hearing occurred when the patient was subjected to a sudden change in pressure (shutting of a car door). Re-operation disclosed that the prosthesis had slipped rearward on the footplate so that there was very poor contact. The prosthesis was again placed in contact with the footplate, all the way forward by the stump of the anterior crus. Again an exceptional improvement in hearing was achieved, lasting for about four weeks. The second re-operation (Case 3) did not reveal the presence of the teflon prosthesis anywhere in the tympanic cavity. The handle was found to be defective, for which reason it has been assumed that the prosthesis has been rejected through

the handle and tympanic membrane. During this operation, the remains of the incus were located in the attic, and it was then interposed in the previously-described manner between the stapes footplate and the handle of the malleus.

In reconstruction of the sound-transmission mechanism during the operations discussed in the paragraphs above, a columella effect has been sought, but it is not impossible that there also is a certain leverage effect developed by the handle of the malleus and the incus prosthesis.

A fracture of the stapes crura was found in Case 21 while the remainder of the ossicular system was found to be normal. In this case, a carefully-dimensioned piece of bone was in-

Diagram No. 5 Series II Group 1

Nos. 1-4... Interposition of a shaped piece of bone between the head of the stapes, the handle of the malleus and the tympanic membrane

the malleus were found, as the result of a cranial trauma. The stapes was intact and mobile. The head of the malleus was found to be tightly wedged in the anterior part of the attic, for which reason the neck of the malleus was severed. The handle of the malleus was then free to move, and the head of the malleus and the incus were removed.

A little cholesteatoma was disclosed in Case 42, and it was found to have caused the destruction of the distal part of the long process of the incus. In addition the head of the malleus was fixed in the attic, while the stapes was intact and mobile. As in the preceding case the neck of the malleus was severed so that the head of the malleus and the incus could then be extracted. In both Cases 41 and 42, shaped pieces of bone were interposed between the stapes and the handle and the tympanic membrane. Good improvement in hearing is seen to have been obtained in both cases, in spite of the lack of the head of the malleus, which is in agreement with the results of experimental research (Elpern and Elbrynd, 1966).

2. Defective stapedia arch

This group consists of 21 operations (including two re-operations). In 13 operations, the incus has been interposed between the stapes foot plate and the handle of the malleus. As it was reported on page 20 the distance from the footplate to the handle corresponds quite precisely in many cases to the distance from the apex of the short process of the incus to the middle of the saddle-shaped articular surface on the body of the incus. The incus has consequently been interposed in these cases, with the handle resting in the middle of the saddle-shaped articulation surface. The remainder of the long process of the incus was first excised, to prevent interference with the promontory. Experimentally the interposition of the incus in this manner has produced optimal transmission of sound in temporal bone preparations (Elbrynd and Elpern 1966).

In two cases (Cases 10 and 12 in Diagram 6) the short process of the incus was found to be too long, and a bit of the apex of the short process was then removed. It then became

DISCUSSION

The following question has previously been stated in the beginning of the preceding section: "It is possible, on the basis of the previously-described clinical and experimental evidence and conclusions, using these audiograms as the criteria, to improve the results of reconstructive surgery on defective ossicular systems?"

The basis for an answer to this question must lie in a comparison between the improvement in hearing achieved in Series I and Series II.

This sort of comparison can be made between each group and series, using the mean average improvement (or loss) of the hearing function at the frequencies 500 1000 and 2000 Hz. The following results can then be tabulated.

- 1 The average improvement in hearing within an entire series or group
- 2 The number of cases where a threshold of hearing of 30 dB (or perhaps 20 dB) or better has been achieved,
- 3 The number of cases where a post-operative air-bone gap of 10 dB (or perhaps 15 or 20 dB) or less has been obtained.

The above-specified data can be seen in the tables on pages 31 and 40. Comparison of the results are clearly to the advantage of Series II.

However tabulations of the mean average improvements in hearing, or the losses, at three frequencies, can only provide limited information on the configuration of the pre-operative and post-operative audiogram.

In addition, special non-parametric statistical methods must be used if a comparison is to be made of the results of several series of operations to improve hearing, and the above mentioned average values are to be used as a basis of comparison.

Results of individual operations to improve hearing are best presented by pre-operative and post-operative audiograms. As Wullstein (1967) suggests, it is consequently natural to compute a pre-operative and a post-operative mean-value audiogram when evaluating the improvements achieved in a series of operations aimed at improving hearing. With such mean-value audiograms, the average improvement (or loss) at each individual frequency may be read directly from the graph.

Mean-value audiograms have been prepared as follows.

- 1 The entire Series I and Series II.

In order to permit the comparison of groups within each series:

2. Series I Group 2 (44 operations) and Series II, Group 1 (intact stapes)

The following comparison is of special interest:

- 3 Series I, Group 2 (30 operations, incus interposition) and Series II, Group 1 (intact stapes)

Within each of these two latter groups, the same technique, i.e. interposition of the incus between the stapes and the tympanic membrane has been used throughout Group 2 of Series I, while a shaped piece of bone has been interposed between the stapes, the tympanic membrane, and the handle of the malleus throughout Group 1 of Series II.

Finally the following comparison may be found interesting:

- 4 Series I, Group 4 and Series II, Group 2 (defective stapedial arch)

Table 7

	Total	Average hearing improvement	Number of cases at or above specified level		Post-operative air-bone gap		
		dB	20 dB level	30 dB level	10 dB or less	15 dB	0 dB
1. Stapes intact	42	25 (29)	23	32	23	31	35
2. Stapes defective	21	29 (36)	9	14	11	16	16

terposed between the long process of the incus and the footplate. It was thus possible to restore the normal function of the ossicular system. Consequently this case does not fit in with the remainder of Group 2, neither in respect to surgical technique nor function.

The resulting improvements in hearing are tabulated in Diagram 6.

In Table 7 the following results for each group can be read.

1 The mean average improvement in hearing

2 The number of cases where the post operative threshold of hearing is 20 dB, 30 dB or better

3 The number of cases where the post operative air-bone gap is 10 dB, 15 dB or 20 dB or less

The figures in parentheses indicate the maximum improvement occurring during the observation period, which is from one month to three years. A total of 11 cases have been observed for six months, 35 were observed for one year and 14 were observed for two years or more.

In Series II as a whole the mean average hearing improvement was 27 dB (Series I 13 dB). A hearing improvement of 10 dB or more was achieved in 54 cases, i.e. in approximately 86 per cent (Series I 63 per cent). In one case a hearing loss exceeding 10 dB occurred, i.e. appx. 1.6 per cent (Series I 12 per cent). After the hearing improvement had culminated which occurs as a rule from one to three months

after the operation, 15 cases (or 24 per cent) were observed to have a hearing loss of 10 dB or more (Series I 30 per cent).

Complications

As previously mentioned, there was one case with a post-operative loss of hearing of 30 dB but this was not of the cochlear type. Vestibular disturbances have not been observed.

Conclusions

The analysis of Series II indicates that:

1 Pieces of bone and the remains of ossicles as used in 57 operations, can permit reconstruction of the ossicular system so as to produce hearing improvements of longer duration, but in a portion of the cases (at least one fourth) the initial improvement in hearing must be expected to deteriorate by more than 10 dB after from one to three months.

2 Good improvement in hearing can be obtained in spite of the lack of the head of the malleus.

3 The use of teflon prostheses initially provides an exceptional improvement in hearing, but it seems more difficult to obtain stable results with this material.

4 Good improvements in hearing have been obtained in Series II either where the stapes was intact or defective.

5 The results obtained now seem to be comparable with those obtained with otosclerosis surgery (Andersen and Warrer 1966).

DISCUSSION

The following question has previously been stated in the beginning of the preceding section: It is possible on the basis of the previously-described clinical and experimental evidence and conclusions, using tone audiograms as the criteria, to improve the results of reconstructive surgery on defective ossicular systems?

The basis for an answer to this question must lie in a comparison between the improvement in hearing achieved in Series I and Series II.

This sort of comparison can be made between each group and series, using the mean average improvement (or loss) of the hearing function at the frequencies 500 1000 and 2000 Hz. The following results can then be tabulated.

- 1 The average improvement in hearing within an entire series or group.
- 2 The number of cases where a threshold of hearing of 30 dB (or perhaps 20 dB) or better has been achieved.
- 3 The number of cases where a post-operative air-bone gap of 10 dB (or perhaps 15 or 20 dB) or less has been obtained.

The above-specified data can be seen in the tables on pages 31 and 40. Comparison of the results are clearly to the advantage of Series II.

However tabulations of the mean average improvements in hearing, or the losses, at three frequencies, can only provide limited information on the configuration of the pre-operative and post-operative audiogram.

In addition, special non-parametric statistical methods must be used if a comparison is to be made of the results of several series of operations to improve hearing, and the above-mentioned average values are to be used as a basis of comparison.

Results of individual operations to improve hearing are best presented by pre-operative and post-operative audiograms. As Wullstein (1967) suggests, it is consequently natural to compute a pre-operative and a post-operative mean-value audiogram when evaluating the improvements achieved in a series of operations aimed at improving hearing. With such mean-value audiograms, the average improvement (or loss) at each individual frequency may be read directly from the graph.

Mean-value audiograms have been prepared as follows:

- 1 The entire Series I and Series II

In order to permit the comparison of groups within each series:

- 2 Series I, Group 2 (44 operations) and Series II, Group 1 (Intact stapes)

The following comparison is of special interest.

- 3 Series I, Group 2 (30 operations, incus interposition) and Series II, Group 1 (Intact stapes).

Within each of these two latter groups, the same technique, i.e. interposition of the incus between the stapes and the tympanic membrane, has been used throughout Group 2 of Series I, while a shaped piece of bone has been interposed between the stapes, the tympanic membrane, and the handle of the malleus throughout Group 1 of Series II.

Finally the following comparison may be found interesting:

- 4 Series I, Group 4 and Series II, Group 2 (defective stapedial arch)

Table 7

	Total	Average hearing improvement	Number of cases at or above specified level		Post-operative air-bone gap		
		dB	20 dB level	30 dB level	10 dB or less	15 dB	20 dB
1 Stapes intact	47	25 (29)	23	3	23	31	35
2 Stapes defective	1	29 (36)	9	14	11	16	16

terposed between the long process of the incus and the footplate. It was thus possible to restore the normal function of the ossicular system. Consequently this case does not fit in with the remainder of Group 2, neither in respect to surgical technique nor function.

The resulting improvements in hearing are tabulated in Diagram 6.

In Table 7 the following results for each group can be read.

1 The mean average improvement in hearing

2. The number of cases where the post operative threshold of hearing is 20 dB 30 dB or better

3 The number of cases where the post operative air bone gap is 10 dB 15 dB or 20 dB or less.

The figures in parentheses indicate the maximum improvement occurring during the observation period which is from one month to three years. A total of 11 cases have been observed for six months, 35 were observed for one year and 14 were observed for two years or more.

In Series II as a whole the mean average hearing improvement was 27 dB (Series I 13 dB). A hearing improvement of 10 dB or more was achieved in 54 cases, i.e. in approximately 86 per cent (Series I 63 per cent). In one case, a hearing loss exceeding 10 dB occurred, i.e. appx. 1.6 per cent (Series I 12 per cent). After the hearing improvement had culminated which occurs as a rule from one to three months

after the operation, 15 cases (or 24 per cent) were observed to have a hearing loss of 10 dB or more (Series I 30 per cent).

Complications

As previously mentioned there was one case with a post-operative loss of hearing of 30 dB, but this was not of the cochlear type. Vestibular disturbances have not been observed.

Conclusions

The analysis of Series II indicates that

1 Pieces of bone and the remains of ossicles, as used in 57 operations, can permit reconstruction of the ossicular system so as to produce hearing improvements of longer duration, but in a portion of the cases (at least one fourth) the initial improvement in hearing must be expected to deteriorate by more than 10 dB after from one to three months.

2. Good improvement in hearing can be obtained in spite of the lack of the head of the malleus.

3 The use of teflon prostheses initially provides an exceptional improvement in hearing, but it seems more difficult to obtain stable results with this material.

4 Good improvements in hearing have been obtained in Series II either where the stapes was intact or defective.

5 The results obtained now seem to be comparable with those obtained with otosclerosis surgery (Andersen and Warrer 1966).

by the means and the standard deviations of the means.

The data obtained in Series I and Series II therefore have been considered to be normally distributed.

Statistical analysis (the *t*-test) indicates that—at a probability level of five per cent—a signifi-

cant improvement in hearing has been obtained for at least five of seven frequencies in Series I and Series II and in the subsidiary groups with the exception of Group 4 of Series I.

Series II

Perusal of these audiograms seems to indicate the following

The mean improvement in hearing at each frequency is greater throughout Series II than in Series I. This is also seen to be valid for a comparison of the subsidiary groups. In particular the hearing improvement in Group 2 of

Series II is significantly greater than for the whole of Group 4 Series I

On the basis of an analysis of a larger number of operations aimed at improving hearing, Wullstein (1967) reports that the data measured can be considered to be normally distributed and for that reason characterized

subsidiary groups indicates—with a five per cent probability level—that a significantly greater improvement in hearing has been obtained in Series II when compared with Series I and likewise in comparison of Group 1 of Series II with Group 2 of Series I (30 operations) and Group 2 of Series II with Group 4 of Series I. On the other hand, there is no significant difference between Group 1 of Series II and group 2 of Series I (44 operations).

However is such a comparison of Series I with Series II and between the subsidiary groups at all permissible?

It is naturally of deciding importance that Series I and Series II are comparable i.e. that the sole variable factor involved is the type of reconstructive surgery performed on the sound conduction mechanism.

It can hardly be stated that this is the case with any great degree of certainty. As it may be seen in the tables on pages 24, 25 and 34 the distribution according to age and aetiology is not the same in both series. To this inconsistency must be added unavoidable variation in the observation periods, and that local anaesthesia was used more frequently in Series I than in Series II. It is difficult to judge whether or not these conditions have had any real influence to the advantage of one series or the other but it should be noted that in reality Series I and Series II constitute a consecutive series, and that the selection of patients and the surgical indications seem to have been the same in both series.

But there is a difference between the two series which is of deciding importance and that difference, which may be discerned in the middle value audiograms, is that the pre-operative air-bone gap is greater in Series II than in Series I. There is no sure explanation for this difference. A greater pre-operative air-bone gap provides the possibility for a greater improvement in hearing, which is seen to be indicated by a regression-correlation analysis to be described below.

The above-mentioned statistical analysis which indicated that greater improvement in

hearing was obtained in Series II and the subsidiary groups than in Series I and its subsidiary groups (with the exception of Group 1 of Series II 44 operations) thus seems hardly relevant, as it has been made on the basis of the absolute improvement in hearing, without regard for the pre-operative air-bone gap.

It is clear that a comparison between the hearing improvements in the two series and their subsidiary groupings must be made on the basis of the relative hearing improvements, i.e. the hearing improvement in respect to the pre-operative air-bone gap.

In Table 8 the percentage of the "closure" of the air-bone gap in each series and the respective subsidiary groups is listed and the calculated differences recorded.

It can be seen that the percentage closure of the air-bone gap is greater in Series II than in Series I. This is especially true for a comparison of Group 4 of Series I with Group 2 of Series II.

Furthermore it is seen that the greatest percentage of closure of the air-bone gap in both series occurs at 250 Hz, and the least at 4000 Hz.

In the third part of the table above, the interposed incus cases in Group 2 of Series I are compared with Group 1 of Series II. It may be recalled that in these cases, the incus was interposed between the stapes and the tympanic membrane, without special effort to achieve contact with the handle of the malleus. In Group 1 of Series II precisely-dimensioned pieces of bone were placed between the handle of the malleus, the tympanic membrane and the stapes, a small groove being provided in the bone fragment to fit the handle of the malleus. At all of the frequencies measured the percentage closure of the air-bone gap was found to be greater in Group 1 of Series II but it is relatively best at 4000 Hz, where the difference amounts to 38 per cent, while the percentage closure ranges from 14 to 22 per cent for the other frequencies. This can presumably be taken as an indication that the experimentally-demonstrated improvement in the

Table 8. *Percentage Closure of the Air Bone Gap*

transmission of the higher frequencies by providing a solid contact between the prosthesis and the handle of the malleus also holds true *in vivo* (see page 33)

Upon comparing Group 4 of Series I with Group 2 of Series II a similar relatively-greater closure of the air-bone gap at 4000 Hz is not demonstrated in Group 2 of Series II. This may be due to the fact that the arch of the stapes is lacking in these cases, which makes difficult the establishment of a sure and really stable contact between the prosthesis and the

footplate of the stapes. An unstable or loose contact will lead to losses in the upper end of the spectrum, which result was predicted by the experimental results obtained with temporal bone preparations.

But, are the relatively greater improvements in hearing in Series II and its subsidiary groups statistically significant? In order to cast light on this problem, regression and correlation analysis has been carried out on this material. Using regression and correlation analysis the functional relationship between the pre-opera-

subsidiary groups indicates—with a five per cent probability level—that a significantly greater improvement in hearing has been obtained in Series II when compared with Series I and likewise in comparison of Group 1 of Series II with Group 2 of Series I (30 operations) and Group 2 of Series II with Group 4 of Series I. On the other hand there is no significant difference between Group 1 of Series II and group 2 of Series I (44 operations).

However is such a comparison of Series I with Series II and between the subsidiary groups at all permissible?

It is naturally of deciding importance that Series I and Series II are comparable i.e. that the sole variable factor involved is the type of reconstructive surgery performed on the sound-conduction mechanism.

It can hardly be stated that this is the case with any great degree of certainty. As it may be seen in the tables on pages 24, 25 and 34 the distribution according to age and aetiology is not the same in both series. To this inconsistency must be added unavoidable variation in the observation periods and that local anaesthesia was used more frequently in Series I than in Series II. It is difficult to judge whether or not these conditions have had any real influence to the advantage of one series or the other but it should be noted that in reality Series I and Series II constitute a consecutive series, and that the selection of patients and the surgical indications seem to have been the same in both series.

But there is a difference between the two series which is of deciding importance, and that difference which may be discerned in the middle value audiograms, is that the pre-operative air-bone gap is greater in Series II than in Series I. There is no sure explanation for this difference. A greater pre-operative air bone gap provides the possibility for a greater improvement in hearing, which is seen to be indicated by a regression-correlation analysis to be described below.

The above mentioned statistical analysis which indicated that greater improvement in

hearing was obtained in Series II and the subsidiary groups than in Series I and its subsidiary groups (with the exception of Group 1 of Series II 44 operations) thus seems hardly relevant as it has been made on the basis of the absolute improvement in hearing, without regard for the pre-operative air-bone gap.

It is clear that a comparison between the hearing improvements in the two series and their subsidiary groupings must be made on the basis of the relative hearing improvements, i.e. the hearing improvement in respect to the pre-operative air-bone gap.

In Table 8 the percentage of the "closure" of the air bone gap in each series and the respective subsidiary groups is listed and the calculated differences recorded.

It can be seen that the percentage closure of the air bone gap is greater in Series II than in Series I. This is especially true for a comparison of Group 4 of Series I with Group 2 of Series II.

Furthermore it is seen that the greatest percentage of closure of the air-bone gap in both series occurs at 250 Hz, and the least at 4000 Hz.

In the third part of the table above, the interposed incus cases in Group 2 of Series I are compared with Group 1 of Series II. It may be recalled that in these cases, the incus was interposed between the stapes and the tympanic membrane, without special effort to achieve contact with the handle of the malleus. But, are the relatively greater improvements in hearing in Series II and its subsidiary groups statistically significant? In order to cast light on this problem, regression and correlation analysis has been carried out on this material. Using regression and correlation analysis the functional relationship between the pre-opera-

Fig. 7 Regression lines for Series I Group (30 operations) and Series II Group I (4 operations)

tive air bone gap and the improvement in hearing obtained can be determined

These analyses indicate that there is statistically sure connection between the pre-operative air bone gap and the hearing improvement obtained, as the regression coefficients for each frequency are significantly different from zero (with a five per cent level of probability) in both series and in the subsidiary groups, with the exceptions of Group 4 of Series I and Group 2 of Series II. The correlation analysis is in agreement with these results.

Fig. 8 Regression lines for Series I Group 2 (30 operations) and Series II Group I (42 operations).

Fig. 9 Regression lines for Series I Group (30 operations) and Series II Group I (42 operations).

In Figures 7 8 9 10 and 11 regression lines for Group 2 of Series I (30 operations) and for Group 1 of Series II have been plotted for the frequencies of 250–4000 Hz in a co-ordinate system having the pre-operative air bone gap as the abscissa, and the hearing improvement obtained as the ordinate. It can be seen that the hearing improvements obtained in Group 1 of Series II seem to have been relatively better—except at 2000 Hz—when the air-bone gap has been of a certain degree of magnitude. An analysis indicates, however

Fig. 10. Regression lines for Series I Group (30 operations) and Series II, Group I (4 operations)

that no significant difference between any of the corresponding regression coefficients can be demonstrated. This is also true for a comparison of the whole of Series I with the whole of Series II and for a comparison of Group 2 of Series I with Group 1 of Series II.

In Fig. 11 the values of the variables used for the regression calculations for each grouping at the frequency of 4000 Hz have been plotted. It can be seen that the two series overlap one another considerably which is in agreement with the statement that there is no statistically significant difference between the regression coefficients.

The reply to the question stated above (page 33) must thus be that only in Group 2 of Series II has it been possible to prove reliably that greater hearing improvements have been obtained than in the corresponding group in Series I. In Group 1 of Series II, it has not been possible to obtain a statistically significant greater improvement in hearing than in Group 2 of Series I.

4000 Hz.

SUMMARY

Etiological and diagnostic aspects of defective linkages in the middle ear ossicular system in ears having an intact tympanic membrane are analyzed.

On the basis of studies of the literature, an outline of the reconstructive surgical methods used on defective ossicles has been compiled, including a comparison of the biological characteristics of the material used for prosthetics.

The following conclusions are drawn

1 Polyethylene is a biologically unsuitable material for use in reconstructing the ossicular system

2 Shaped pieces of bone, remains of ossicles and metal wire are suitable materials,

3 Methods involving interposition and transposition often result in good improvements in hearing.

A series of 67 patients (Series I 71 affected ears) treated with a total of 81 ossiculo-plastic operations, is analyzed in respect to aetiology, diagnosis, surgical treatment, and the results obtained. It is confirmed that polyethylene is an unsuitable material for prosthetics, in contrast to bone fragments and the remains of ossicles. Using these materials in an interposition technique, a number of good improvements have been obtained but the hearing improvements are generally not satisfactory. This is especially true when there is a defective stapedial arch.

In the other clinical series, Series II consist

ing of 55 patients (58 affected ears, treated with 63 operations) an attempt has been made to achieve greater hearing improvements by making use of the following:

1 Clinical experience gleaned from the literature and from Series I

2 Mechanical relationship revealed in a series of sound transmission experiments on dissected preparations of temporal bones (Elbrønd and Elpern 1965, 1966 and Elpern and Elbrønd 1966) to be of deciding importance in achievement of optimal operation of the transmission mechanism.

Series II like Series I includes only cases where the defective ossicular system was concealed behind an intact tympanic membrane. Series II is also analyzed in respect to aetiology, diagnosis, treatment, and results.

On the basis of mean value audiograms for both series and the comparable subdivisions of both series, it is shown that there is apparently a greater improvement in hearing for Series II than for Series I at least in cases having a defective stapedial arch. A statistical regression and correlation analysis, however, reveals that when the pre-operative air bone gap is taken into consideration—the air bone gap is somewhat greater on the average in Series II—there is no significantly greater improvement for Series II Group I (the group where the stapes is intact) when compared with the corresponding group in Series I.

SUMMARY

Aetiological and diagnostic aspects of defective linkages in the middle ear ossicular system in ears having an intact tympanic membrane are analyzed.

On the basis of studies of the literature an outline of the reconstructive surgical methods used on defective ossicles has been compiled, including a comparison of the biological characteristics of the material used for prosthetics.

The following conclusions are drawn

1 Polyethylene is a biologically unsuitable material for use in reconstructing the ossicular system

2. Shaped pieces of bone, remains of ossicles, and metal wire are suitable materials,

3 Methods involving interposition and transposition often result in good improvements in hearing

A series of 67 patients (Series I 71 affected ears) treated with a total of 81 ossiculo-plastic operations is analyzed in respect to aetiology, diagnosis, surgical treatment, and the results obtained. It is confirmed that polyethylene is an unsuitable material for prosthetics, in contrast to bone fragments and the remains of ossicles. Using these materials in an interposition technique, a number of good improvements have been obtained but the hearing improvements are generally not satisfactory. This is especially true when there is a defective stapedial arch.

In the other clinical series, Series II consist

ing of 55 patients (58 affected ears, treated with 63 operations) an attempt has been made to achieve greater hearing improvements by making use of the following:

1 Clinical experience gleaned from the literature, and from Series I

2 Mechanical relationship revealed in a series of sound-transmission experiments on dissected preparations of temporal bones (Elbrønd and Elperm 1965 1966 and Elperm and Elbrønd, 1966) to be of deciding importance in achievement of optimal operation of the transmission mechanism.

Series II like Series I includes only cases where the defective ossicular system was concealed behind an intact tympanic membrane. Series II is also analyzed in respect to aetiology, diagnosis, treatment and results.

On the basis of mean value audiograms for both series and the comparable subdivisions of both series, it is shown that there is apparently a greater improvement in hearing for Series II than for Series I at least in cases having a defective stapedial arch. A statistical regression and correlation analysis, however, reveals that when the pre-operative air-bone gap is taken into consideration—the air-bone gap is somewhat greater on the average in Series II—there is no significantly greater improvement for Series II Group 1 (the group where the stapes is intact) when compared with the corresponding group in Series I

SUMMARY

Aetiological and diagnostic aspects of defective linkages in the middle ear ossicular system in ears having an intact tympanic membrane are analyzed.

On the basis of studies of the literature an outline of the reconstructive surgical methods used on defective ossicles has been compiled, including a comparison of the biological characteristics of the material used for prosthetics.

The following conclusions are drawn

1 Polyethylene is a biologically unsuitable material for use in reconstructing the ossicular system,

2 Shaped pieces of bone remains of ossicles and metal wire are suitable materials,

3 Methods involving interposition and transposition often result in good improvements in hearing

A series of 67 patients (Series I 71 affected ears) treated with a total of 81 ossiculo-plastic operations, is analyzed in respect to aetiology, diagnosis, surgical treatment, and the results obtained. It is confirmed that polyethylene is an unsuitable material for prosthetics, in contrast to bone fragments and the remains of ossicles. Using these materials in an interposition technique, a number of good improvements have been obtained but the hearing improvements are generally not satisfactory. This is especially true when there is a defective stapedial arch.

In the other clinical series, Series II consist

ing of 55 patients (58 affected ears treated with 63 operations) an attempt has been made to achieve greater hearing improvements by making use of the following—

1 Clinical experience gleaned from the literature and from Series I

2 Mechanical relationship revealed in a series of sound transmission experiments on dissected preparations of temporal bones (Elbrønd and Elpern, 1965 1966 and Elpern and Elbrønd, 1966) to be of deciding importance in achievement of optimal operation of the transmission mechanism.

Series II like Series I includes only cases where the defective ossicular system was concealed behind an intact tympanic membrane. Series II is also analyzed in respect to aetiology, diagnosis, treatment, and results.

On the basis of mean value audiograms for both series and the comparable subdivisions of both series, it is shown that there is apparently a greater improvement in hearing for Series II than for Series I at least in cases having a defective stapedial arch. A statistical regression and correlation analysis, however, reveals that when the pre-operative air-bone gap is taken into consideration—the air-bone gap is somewhat greater on the average in Series II—there is no significantly greater improvement for Series II Group 1 (the group where the stapes is intact) when compared with the corresponding group in Series I.

Locacorten-Vioform[®] eardrops

- antifungal as well as antibacterial
- clear, penetrating, residue-free solution
- precise control single-drop dispenser

exerts a powerful local action which quickly relieves itching and tenderness and reduces swelling thus improving access of the antiseptic for rapid elimination of bacterial and fungal infection • Available in 75 ml plastic dispensers

THE XVIIITH CONGRESS OF THE SCANDINAVIAN OTO-LARYNGOLOGICAL SOCIETY

Helsingør Denmark, June 27-30 1969

The Congress was held at Marienlyst, Helsingør. The Congress Committee consisted of Professor *H. C. Andersen*, President, Professor *H. K. Kristensen*, Vice-president; Dr *O. Bentzen*, Secretary, Dr *H. Sørensen*, Cashier, Professor *O. Jepsen*, Editor and Dr *O. Elbrønd*, Assistant Editor. The discussion was limited to the following topics.

Function of the Eustachian Tube

Disorders of the Salivary Glands

Phoniatry

Objective Methods of Assessing the Hearing Ability

In addition, a Scientific Exhibition was held.

The Congress was attended by 230 active (Denmark 76, Finland, 30, Iceland, 2, Norway 49, Sweden, 78) and 162 passive members.

At the Official Opening, the President addressed the Congress as follows.

On behalf of the Congress Board and the Danish Society of Oto-Laryngology I have the honour and pleasure to welcome you to this Seventeenth Congress of the Scandinavian Oto-Laryngological Society.

It is a special pleasure for the Society to welcome for the first time official members from Iceland to join our Society.

This meeting will show several breaks of traditions. The motivation has been to secure as much unity in this gathering and in its scientific activities as possible. We have followed

the rules of the classic French theatre: The unities of time, place and action. In our choice of topics we have aimed at demonstrating the scope of our field and our intentions to comply with demands from the subspecialties ranging under otolaryngology.

As far as I know, Scandinavian otolaryngologists met for the first time as members of the Section of Otology at the International Medical Congress, which was held in Copenhagen in 1884.

Only 30 years later our Society was founded. Amongst its founders and its early members, three Danes are still alive, Blegvad, Mygind and Thornval.

In the hope that we shall be able to live up to that ardent enthusiasm which our predecessors entertained for otolaryngology and its Scandinavian co-operation I declare this Congress open.

Entertainments during the Congress

On Friday June 27 the members and their ladies were invited by the Danish Oto-Laryngological Society to a cocktail party and souper at the Marienlyst.

The banquet was held at the same place on Sunday June 29.

On Saturday June 28 the ladies visited Copenhagen and had lunch at Tivoli.

On Sunday June 29 the ladies visited the Art Gallery Louisiana and had lunch at Restaurant Hystens Perle.

THE XVIII TH CONGRESS OF THE SCANDINAVIAN OTO-LARYNGOLOGICAL SOCIETY

Helsingør Denmark, June 27 30 1969

The Congress was held at Marenlyst, Helsingør. The Congress Committee consisted of Professor H. C. Andersen, President; Professor H. K. Kristensen, Vice-president; Dr. O. Bentzen, Secretary; Dr. H. Sørensen, Cashier; Professor O. Jepsen, Editor; and Dr. O. Elbrønd, Assistant Editor. The discussion was limited to the following topics:

Function of the Eustachian Tube

Disorders of the Salivary Glands

Phoniatrics

Objective Methods of Assessing the Hearing Ability

In addition, a Scientific Exhibition was held.

The Congress was attended by 230 active (Denmark, 76; Finland, 30; Iceland, Norway, 49; Sweden, 78) and 162 passive members.

At the Official Opening, the President addressed the Congress as follows:

On behalf of the Congress Board and the Danish Society of Oto-Laryngology I have the honour and pleasure to welcome you to this Seventeenth Congress of the Scandinavian Oto-Laryngological Society.

It is a special pleasure for the Society to welcome for the first time official members from Iceland to join our Society.

This meeting will show several breaks of tradition. The motivation has been to secure as much unity in this gathering and in its scientific activities as possible. We have followed

the rules of the classic French theatre: The unities of time, place and action. In our choice of topics we have aimed at demonstrating the scope of our field and our intentions to comply with demands from the subspecialties ranging under otolaryngology.

As far as I know, Scandinavian otolaryngologists met for the first time as members of the Section of Otolaryngology at the International Medical Congress, which was held in Copenhagen in 1884.

Only 30 years later, our Society was founded. Amongst its founders and its early members, three Danes are still alive, Blegvad, Mygind and Thomsen.

In the hope that we shall be able to live up to that ardent enthusiasm which our predecessors entertained for otolaryngology and its Scandinavian co-operation I declare this Congress open.

Entertainments during the Congress

On Friday June 27 the members and their ladies were invited by the Danish Oto-Laryngological Society to a cocktail party and supper at the Marenlyst.

The banquet was held at the same place on Sunday June 29.

On Saturday June 28 the ladies visited Copenhagen and had lunch at Thvøll.

On Sunday June 29 the ladies visited the Art Gallery Louisiana and had lunch at Restaurant Kystens Perle.

MEETING OF THE COUNCIL OF THE SCANDINAVIAN OTO-LARYNGOLOGICAL SOCIETY

The meeting took place at the Marienlyst on June 27 at 11 a. m.

The following members of the Council were present. H. C. Andersen, H. K. Kristensen and K. A. Thomsen representing Denmark. T. Palva and U. Siirala representing Finland. E. Thorsteinsson representing Iceland. G. Djupesland and T. Leegaard representing Norway and G. Herberts and G. Nilsson representing Sweden.

The President of the Congress, Professor H. C. Andersen was elected Chairman.

G. Herberts suggested that the next Congress should be held in Göteborg in 1972. The Council accepted the Swedish invitation with gratitude. It was proposed that Professor Gösta Herberts should act as President and Professor Hans Engström as Vice-President. This proposal was carried unanimously by the Council.

It was decided that the Past President, the Past Secretary and the Past Treasurer should always attend the meetings of the Council.

The Council decided to recommend the business meeting to accept a Finnish proposal that in certain cases of "difficulties in commu-

nication" English should be accepted as an alternative Congress language.

BUSINESS MEETING OF THE CONGRESS

This meeting took place at Marienlyst on June 29 at 4 p. m.

The President announced the Swedish invitation for the next Congress to be held in Göteborg in 1972. The Congress accepted the invitation and unanimously agreed to the Swedish proposal that the next Congress Committee should consist of Professor G. Herberts, President, Professor H. Engström, Vice-president, and Dr. Hallén, Secretary.

Decisions upon the date, the programme and the publications of the transactions were left to this committee.

It was decided that the annual subscription fee should remain unchanged at the equivalent of 25 Swedish kronor.

It was decided that in special cases of difficulties of communication, a non-Scandinavian language may be accepted as an alternative Congress language.

The Bylaws of the Scandinavian Oto-Laryngological Society remained unchanged (printed in Acta-Otolaryng. Suppl. 224).

ELECTRON-MICROSCOPIC EXAMINATION OF THE INNER
EAR OF THE PIGEON

G. F. Dohleman

*From the Department of Otolaryngology the University of Toronto,
and the Defence Research Establishment Toronto Canada*

The results are presented of electron-microscopic and experimental studies on the inner ear of the pigeon.

The relatively simple principle of the morphological and functional pattern in different parts of the inner ear is demonstrated. It is suggested that a comparison with equivalent structures in other species might be of value for their functional appreciation.

This presentation is intended to give a short survey of the mechanism of endolymphatic metabolism in the inner ear and as a preliminary report to evaluate the importance of the endolymph to the function of the sensory epithelium based on some recent findings and view points.

In the ampullae of the semicircular canals there are regions of specialized cells surrounding the hair-cell area on the cristae. They have been well known and morphologically described since the beginning of ear histology and have been generally believed to be secretory producing the endolymph filling the whole membranous inner ear. One of these regions is the *planum semilunatum*, situated in the lateral wall of the ampulla seen in the microscope as a layer of high cylindrical cells. That these cells actually are secretory has previously been shown by means of autoradiography (Dohleman *et al.* 1959). Parenterally injected radioactive sulphur is accumulated in these cells in pigeons and later the labelled substances appear as a secretion in the endolymph. This secretion has been assumed to contain acid

mucopolysaccharides based on the finding that they are labelled with sulphur and have been shown in the endolymph and cupula with appropriate staining techniques (Beisinger 1961; Wiatlocki & Ladman, 1955) as well as chemically (Vilstrup *et al.*, 1955).

However the parenteral injections give a prolonged feeding through the blood supply to the cells to be studied. This makes it difficult to follow step by step the fate of the isotopes in the cell through the active organelles to the final secretional products. For this reason a "pulse labelling" procedure has been used by injecting a small amount of the labelled isotope into the perilymph. The isotope is left in the perilymph surrounding the membranous ampulla for 2-3 minutes and is then removed by flushing with an artificial perilymph. Different time intervals between the exposure to the isotope and fixation *in situ* reveal the way through the membranous wall to the different organelles in the secretional cells and eventually the endolymph. Slide 1 is an illustration of some *planum semilunatum* cells "pulse-labelled" with radioactive sulphur and a time interval of 10 minutes. The autoradiographic silver grains are then found at the level of the Golgi apparatus of the cells.

However in order to study the nature of the secretion the "pulse labelling" is also used for amino acids and sugars on the assumption that the secretional products are glycoproteins. Further other methods have been used to demonstrate the mucopolysaccharides in the pro-

Supported by grants from the National Research Council, Grant No 502-279-50 and the Department of Supply and Services, Contract Ser. GR 8-14.

ducts of the planum semilunatum cells. If treated with colloidal iron ruthenium red or lanthanum all these methods give the same results, showing vesicles conglomerating to vacuoles towards the endolymphatic surface of the cell. Further with this method it can be demonstrated that the secretion forms a net work of mucopolysaccharides in the endolymph (Slide 2). In light microscopy the mucopolysaccharides can be seen in the endolymph as a loose network filling the whole endolymphatic system of the vestibular apparatus. In a section of the cupular substance (Slide 3) impregnated with colloidal iron the meshwork of the protein skeleton of the cupula chemically analysed by Iurato as belonging to the keratin group, a layer of polysaccharides has been precipitated on all surface of the trabecles of the cupula and is partly found also in the spaces between them.

It has previously been pointed out that the cells on the slopes of the crista are morphologically different from those of the planum semilunatum (Dohleman 1964). Already Retzius saw them and described them as containing different kinds of cells. However Iwata (1924) called these parts of the walls "*regiones secretoriae*" and pointed out that these areas actually surround the hair-cell regions in the ampulla as well as the utricle. Ficandl & Saxén (1951) also mentioned morphological differences in these cell regions, but regarded them as a sign of different stages in a secretory cycle in the same way as it has been described for the goblet cells in the mucous membranes. However in the utricular walls there are also two kinds of cells. This has been described by Smith (1956). Dark and light cells on the slopes of the cristae in the guinea pig have also been described by Wersäll. In experiments some years ago in which the wall of the membranous ampulla had been cut resulting in an interchange between endolymph and perilymph it became evident that the dark cells changed in appearance. In electron-microscopy it could be seen that these cells were filled with large vacuoles.

As is well known Smith *et al* (1954) were able to analyse the labyrinthine fluids by modern methods. Their results showed that the sodium concentration in the perilymph was high and about the same as in all other extracellular fluids and the potassium content was correspondingly low. The endolymph is also an extracellular fluid but it showed a totally different composition with regard to these electrolyte ions. The endolymph has 30 times more potassium than the perilymph and 10 times less sodium.

A pertinent problem was therefore to find some methods to show the mechanism by which this unique electrolyte composition is created and maintained, what structures are involved and the purpose of this strange electrolyte concentration.

When examined under the electron microscope the structure of the dark cells shows a thick brim of microvilli on the endolymphatic surface of the cells, the cytoplasm is filled with mitochondria and the cell shows a labyrinth of indentations of the cell membrane at the base (Dohleman, 1965). All this is in accordance with a functional activity of moving fluid and solutes from the endolymph. Several methods were used to demonstrate the validity of this assumption. When methylene blue was injected into the endolymph, several distinct blue dots were found in the dark cells 1-2 minutes after the injection. After 10 minutes, small drops of the dye were seen to fill a great part of the cytoplasmic space when studied under the light microscope, and 1-1½ hours after the injections, methylene blue was found in the capillary walls. Injections of radioactively labelled sodium seemed also to indicate uptake in the dark cells, but these experiments must be reconfirmed to be significant. However if the dark cells absorb sodium, it would be reasonable to assume that these cells would contain more sodium than the surrounding cells. On this assumption, the sodium was precipitated with antimony compounds by the method of Kornick (1962). Together these different experiments appear to indicate that

the dark cells selectively remove sodium from the endolymph.

It is, however generally accepted that "pumping" of sodium in one direction is accompanied by an equivalent movement of potassium ions in the opposite direction. This would then result in an increase in potassium and a depletion of sodium in the endolymph. This is a highly energy-consuming process. As is well known, the mitochondria are the main producers of energy for the functions of the cells. The enormous amount of mitochondria in the dark cells indicates the high production of energy by these cells, explaining the origin of energy for their function as an ion-exchange "pump".

The areas containing dark cells surround the sensory cell regions in all the ampullae as well as the utricle. This seems to indicate that the function of the dark cells which appear to create this unique potassium-sodium concentration of the endolymph must be of great importance to the function of the sensory cells. It is also well known, from the investigations of Davis *et al.* (1955) and many others, that an increase in sodium concentration as well as a decrease in potassium are harmful to the function of the hair cells and can even be dangerous to the survival of these cells.

The cells for the creation and maintenance of this special electrolyte concentration in the ampullae therefore seem to be concentrated in the regions close to the cristae and around the maculae. However it would be of considerable importance to know if and how this ion concentration can be maintained also in other areas of the endolymph system at some distance from the dark-cell areas, for example, in the relatively long semicircular canals. It would seem reasonable if some leakage of ions would occur through the thin membranous canal walls separating endo- and perilymph (Meyer 1951) with the high difference in concentration of ions in these two fluid systems.

Some experiments were therefore performed (Dahlman & Radomski, 1968) to investigate the ability of the membranous canal walls to

maintain the ion concentrations in the endolymph.

1. The anterior canal of the pigeon was clamped at both ends after special precautions to maintain the vascular blood supply to the canal. In these experiments, the potassium concentration remained unchanged even after a period of 3-4 hours.

2. The canal together with the blood vessels were clamped at both ends of the canal. Then the potassium concentration fell rapidly and became equal to the perilymph within 2-2½ hours.

3. The endolymph of the canal was substituted with a solution of an artificial perilymph. The canal was then clamped, but the vascular supply was left intact. In this case, there was a slow increase in the potassium content in the canal.

Thus, these experiments have evidenced that even in the canals with its flat and thin "indifferent" epithelium the ability to maintain the specific ion concentration of endolymph is present. It might therefore be assumed that the non-specific epithelium of all the walls of the membranous inner ear have this same functional ability.

Between the dark cells are cells with a much lighter cytoplasm. These cells have no microvilli, but a large Golgi apparatus and vesicles and inclusions indicating a secretory function. Experiments with colloidal iron and other methods of staining macropolysaccharides proved that they were secreting these substances.

It has been shown by several investigators that the electrolyte concentration is the same in the endolymph when taken from the vestibular apparatus and from the cochlea, the two parts of the inner ear without a functional communication. It must therefore be of importance to investigate the morphology first of all the cells responsible for the ion exchange, the dark cells, secondly also the light cells with the ability to produce a secretion into the endolymph, and finally to compare these two cell types and their function in the two parts

ducts of the planum semilunatum cells. If treated with colloidal iron ruthenium red or lanthanum all these methods give the same results, showing vesicles conglomerating to vacuoles towards the endolymphatic surface of the cell. Further with this method it can be demonstrated that the secretion forms a network of mucopolysaccharides in the endolymph (Slide 2). In light microscopy the mucopolysaccharides can be seen in the endolymph as a loose network filling the whole endolymphatic system of the vestibular apparatus. In a section of the cupular substance (Slide 3) impregnated with colloidal iron the meshwork of the protein skeleton of the cupula chemically analysed by Iurato as belonging to the keratin group, a layer of polysaccharides has been precipitated on all surface of the trabecles of the cupula and is partly found also in the spaces between them.

It has previously been pointed out that the cells on the slopes of the crista are morphologically different from those of the planum semilunatum (Dohlman 1964). Already Retzius saw them and described them as containing different kinds of cells. However Iwata (1924) called these parts of the walls "regiones secretoriae" and pointed out that these areas actually surround the hair-cell regions in the ampulla as well as the utricle. Fieandt & Saxén (1951) also mentioned morphological differences in these cell regions, but regarded them as a sign of different stages in a secretional cycle in the same way as it has been described for the goblet cells in the mucous membranes. However in the utricular walls there are also two kinds of cells. This has been described by Smith (1956). Dark and light cells on the slopes of the cristae in the guinea pig have also been described by Wersäll. In experiments some years ago in which the wall of the membranous ampulla had been cut resulting in an interchange between endolymph and perilymph it became evident that the dark cells changed in appearance. In electron microscopy it could be seen that these cells were filled with large vacuoles.

As is well known, Smith *et al* (1954) were able to analyse the labyrinthine fluids by modern methods. The endolymph has 30 times more potassium than the perilymph and 10 times less sodium.

A pertinent problem was therefore to find some methods to show the mechanism by which this unique electrolyte composition is created and maintained, what structures are involved and the purpose of this strange electrolyte concentration.

When examined under the electron microscope the structure of the dark cells shows a thick brim of microvilli on the endolymphatic surface of the cells. The cytoplasm is filled with mitochondria and the cell shows a labyrinth of indentations of the cell membrane at the base (Dohlman, 1965). All this is in accordance with a functional activity of moving fluid and solutes from the endolymph. Several methods were used to demonstrate the validity of this assumption. When methylene blue was injected into the endolymph, several distinct blue dots were found in the dark cells 1-2 minutes after the injection. After 10 minutes, small drops of the dye were seen to fill a great part of the cytoplasmic space when studied under the light microscope, and 1-1½ hours after the injections, methylene blue was found in the capillary walls. Injections of radioactively labelled sodium seemed also to indicate uptake in the dark cells, but these experiments must be reconfirmed to be significant. However if the dark cells absorb sodium, it would be reasonable to assume that these cells would contain more sodium than the surrounding cells. On this assumption, the sodium was precipitated with antimony compounds by the method of Komnick (1962). Together these different experiments appear to indicate that

the dark cells selectively remove sodium from the endolymph.

It is, however, generally accepted that "pumping" of sodium in one direction is accompanied by an equivalent movement of potassium ions in the opposite direction. This would then result in an increase in potassium and a depletion of sodium in the endolymph. This is a highly energy-consuming process. As is well known, the mitochondria are the main producers of energy for the functions of the cells. The enormous amount of mitochondria in the dark cells indicates the high production of energy by these cells, explaining the origin of energy for their function as an ion-exchange pump.

The areas containing dark cells surround the sensory cell regions in all the ampullae as well as the utricle. This seems to indicate that the function of the dark cells which appear to create this unique potassium-sodium concentration of the endolymph must be of great importance to the function of the sensory cells. It is also well known, from the investigations of Davis *et al.* (1955) and many others, that an increase in sodium concentration as well as a decrease in potassium are harmful to the function of the hair cells and can even be dangerous to the survival of these cells.

The cells for the creation and maintenance of this special electrolyte concentration in the ampullae therefore seem to be concentrated in the regions close to the crista and around the maculae. However it would be of considerable importance to know if and how this ion concentration can be maintained also in other areas of the endolymph system at some distance from the dark-cell areas, for example, in the relatively long semicircular canals. It would seem reasonable if some leakage of ions would occur through the thin membranous canal walls separating endo- and perilymph (Meyer, 1951), with the high difference in concentration of ions in these two fluid systems.

Some experiments were therefore performed (Dohlman & Radowski, 1968) to investigate the ability of the membranous canal walls to

maintain the ion concentrations in the endolymph.

1. The anterior canal of the pigeon was clamped at both ends after special precautions to maintain the vascular blood supply to the canal. In these experiments, the potassium concentration remained unchanged even after a period of 3-4 hours.

2. The canal together with the blood vessels were clamped at both ends of the canal. Then the potassium concentration fell rapidly and became equal to the perilymph within 2-2½ hours.

3. The endolymph of the canal was substituted with a solution of an artificial perilymph. The canal was then clamped, but the vascular supply was left intact. In this case, there was a slow increase in the potassium content in the canal.

Thus, these experiments have evidenced that even in the canals with its flat and thin "indifferent" epithelium the ability to maintain the specific ion concentration of endolymph is present. It might therefore be assumed that the non-specific epithelium of all the walls of the membranous inner ear have this same functional ability.

Between the dark cells are cells with a much lighter cytoplasm. These cells have no microvilli, but a large Golgi apparatus and vesicles and inclusions indicating a secretory function. Experiments with colloidal iron and other methods of staining macropolysaccharides proved that they were secreting these substances.

It has been shown by several investigators that the electrolyte concentration is the same in the endolymph when taken from the vestibular apparatus and from the cochlea, the two parts of the inner ear without a functional communication. It must therefore be of importance to investigate the morphology first of all the cells responsible for the ion exchange, the dark cells, secondly also the light cells with the ability to produce a secretion into the endolymph, and finally to compare these two cell types and their function in the two parts

ducts of the planum semilunatum cells. If treated with colloidal iron ruthenium red or lanthanum, all these methods give the same results, showing vesicles conglomerating to vacuoles towards the endolymphatic surface of the cell. Further with this method it can be demonstrated that the secretion forms a network of mucopolysaccharides in the endolymph (Slide 2). In light microscopy the mucopolysaccharides can be seen in the endolymph as a loose network filling the whole endolymphatic system of the vestibular apparatus. In a section of the cupular substance (Slide 3) impregnated with colloidal iron the meshwork of the protein skeleton of the cupula chemically analysed by Iurato as belonging to the keratin group, a layer of polysaccharides has been precipitated on all surface of the trabecles of the cupula and is partly found also in the spaces between them.

It has previously been pointed out that the cells on the slopes of the crista are morphologically different from those of the planum semilunatum (Dohleman 1964). Already Retzius saw them and described them as containing different kinds of cells. However Iwata (1924) called these parts of the walls "regiones secretoriae" and pointed out that these areas actually surround the hair-cell regions in the ampulla as well as the utricle. Fieandt & Saxén (1951) also mentioned morphological differences in these cell regions, but regarded them as a sign of different stages in a secretory cycle in the same way as it has been described for the goblet cells in the mucous membranes. However in the utricular walls there are also two kinds of cells. This has been described by Smith (1956). Dark and light cells on the slopes of the cristae in the guinea pig have also been described by Wersäll. In experiments some years ago in which the wall of the membranous ampulla had been cut resulting in an interchange between endolymph and perilymph it became evident that the dark cells changed in appearance. In electron microscopy it could be seen that these cells were filled with large vacuoles.

As is well known Smith *et al* (1954) were able to analyse the labyrinthine fluids by modern methods. Their results showed that the sodium concentration in the perilymph was high and about the same as in all other extracellular fluids, and the potassium content was correspondingly low. The endolymph is also an extracellular fluid but it showed a totally different composition with regard to these electrolyte ions. The endolymph has 30 times more potassium than the perilymph and 10 times less sodium.

A pertinent problem was therefore to find some methods to show the mechanism by which this unique electrolyte composition is created and maintained what structures are involved and the purpose of this strange electrolyte concentration.

When examined under the electron microscope the structure of the dark cells shows a thick brim of microvilli on the endolymphatic surface of the cells. The cytoplasm is filled with mitochondria and the cell shows a labyrinth of indentations of the cell membrane at the base (Dohleman 1965). All this is in accordance with a functional activity of moving fluid and solutes from the endolymph. Several methods were used to demonstrate the validity of this assumption. When methylene blue was injected into the endolymph, several distinct blue dots were found in the dark cells 1-2 minutes after the injection. After 10 minutes, small drops of the dye were seen to fill a great part of the cytoplasmic space when studied under the light microscope and 1-1½ hours after the injections, methylene blue was found in the capillary walls. Injections of radioactively labelled sodium seemed also to indicate uptake in the dark cells, but these experiments must be reconfirmed to be significant. However if the dark cells absorb sodium it would be reasonable to assume that these cells would contain more sodium than the surrounding cells. On this assumption the sodium was precipitated with antimony compounds by the method of Kohnick (1962). Together these different experiments appear to indicate that

the dark cells selectively remove sodium from the endolymph.

It is, however, generally accepted that pumping of sodium in one direction is accompanied by an equivalent movement of potassium ions in the opposite direction. This would then result in an increase in potassium and a depletion of sodium in the endolymph. This is a highly energy-consuming process. As is well known, the mitochondria are the main producers of energy for the functions of the cells. The enormous amount of mitochondria in the dark cells indicates the high production of energy by these cells, explaining the origin of energy for their function as an ion-exchange "pump".

The areas containing dark cells surround the sensory cell regions in all the ampullae as well as the utricle. This seems to indicate that the function of the dark cells which appear to create this unique potassium-sodium concentration of the endolymph must be of great importance to the function of the sensory cells. It is also well known, from the investigations of Davis *et al.* (1955) and many others, that an increase in sodium concentration as well as a decrease in potassium are harmful to the function of the hair cells and can even be dangerous to the survival of these cells.

The cells for the creation and maintenance of this special electrolyte concentration in the ampullae therefore seem to be concentrated in the regions close to the crurae and around the maculae. However, it would be of considerable importance to know if and how this ion concentration can be maintained also in other areas of the endolymph system at some distance from the dark-cell areas, for example in the relatively long semicircular canals. It would seem reasonable if some leakage of ions would occur through the thin membranous canal walls separating endo- and perilymph (Meyer 1951) with the high difference in concentration of ions in these two fluid systems.

Some experiments were therefore performed (Dohlman & Radomski, 1968) to investigate the ability of the membranous canal walls to

maintain the ion concentrations in the endolymph.

1 The anterior canal of the pigeon was clamped at both ends after special precautions to maintain the vascular blood supply to the canal. In these experiments, the potassium concentration remained unchanged even after a period of 3-4 hours.

2 The canal together with the blood vessels were clamped at both ends of the canal. Then the potassium concentration fell rapidly and became equal to the perilymph within 2-2½ hours.

3 The endolymph of the canal was substituted with a solution of an artificial perilymph. The canal was then clamped, but the vascular supply was left intact. In this case there was a slow increase in the potassium content in the canal.

Thus, these experiments have evidenced that even in the canals with its flat and thin "indifferent" epithelium the ability to maintain the specific ion concentration of endolymph is present. It might therefore be assumed that the non-specific epithelium of all the walls of the membranous inner ear have this same functional ability.

Between the dark cells are cells with a much lighter cytoplasm. These cells have no microvilli, but a large Golgi apparatus and vesicles and inclusions indicating a secretory function. Experiments with colloidal iron and other methods of staining mucopolysaccharides proved that they were secreting these substances.

It has been shown by several investigators that the electrolyte concentration is the same in the endolymph when taken from the vestibular apparatus and from the cochlea, the two parts of the inner ear without a functional communication. It must therefore be of importance to investigate the morphology first of all the cells responsible for the ion exchange, the dark cells; secondly also the light cells with the ability to produce a secretion into the endolymph, and finally to compare these two cell types and their function in the two parts

of the inner ear. This comparison appeared to be more easily interpreted in the simple ear of the pigeon than in higher animals.

In the cochlea of birds, the part of the wall in the cochlear duct which corresponds to the stria vascularis in mammals is the so-called tegmentum vasculosum. Already in light microscopy it is seen that this structure is composed of the regular sequence of dark and light cells demonstrated in the vestibular apparatus. This has also recently been pointed out by Jahnke *et al* (1969). In electron microscopy it is evident that the dark cells have the same characteristics as those in the ampullae: a brush of microvilli, the cytoplasm is filled with mitochondria, and the base of the cell is deeply indented. Experiments with methylene blue shows the same uptake of the dye in the vacuoles, and this can be confirmed under the electron microscope. In all probability the dark cells in the two parts of the ear therefore appear to have a basically similar function.

The light cells in the cochlea, however, show some significant differences as compared with those in the vestibular apparatus. They appear more "empty" they have a small Golgi apparatus and only a few inclusions, mostly in the upper parts of the cell, close to the endolymphatic surface. However, that they are secreting cells is demonstrated in Slide 4 showing a rounded droplet just passing through the cell membrane. In this case, the droplet contains lipids, confirmed by staining with Sudan black, but there are other adjacent inclusions which also seem to be on their way to extrusion. Treated with colloidal iron these cells show very little of mucopolysaccharides in their secretory products.

In conclusion these studies have shown that the whole endolymphatic system is well supplied with epithelial cells with special functions. The most important seems to be the dark cells, which have the ability to remove sodium from the endolymph and at the same time increase the potassium concentration. It is well known that this is a necessary condition for the function of the hair cells, which explains the loca-

tion of the dark cell areas in closest vicinity to the different regions of sensory cells.

It has been assumed by several investigators that the endolymph should have the function of carrying nutrients and oxygen to the hair cells. This assumption is based on the misconception that the hair cells in the organ of Corti had no access to a direct nutrition from blood capillaries. Those which were found in the vicinity of the spiral vessels, seemed to be too far away from the cells to provide a sufficient nutritional supply. The experiments by Lawrence (1966) showed that a blocking of these spiral vessels under the organ of Corti resulted in a destruction of the hair cells in spite of an intact stria vascularis. On the other hand, a destruction of the stria vascularis had no effect on the hair cells. The sensory cell areas of the vestibular apparatus are all well supplied by a highly developed capillary network. This excludes the possibility of any hypothetical by-pass over the endolymph as a route for nutrition of their hair cells. To assume one mechanism for nutrition of the vestibular hair cells from the adjacent capillaries and another through the endolymph for the cochlear sense organ therefore seems rather far fetched. Further the investigations by Silverstein (1966) has evidenced that the glucose concentration of the endolymph is only one tenth of that of the blood. Finally Misrahy's measurements of the oxygen tension in the cochlea showed that close to the hair cells the values were so low that they must be regarded as incompatible with an oxygen uptake from the endolymph (Ranck, 1966).

One important problem is the role of the mucopolysaccharides in the vestibular part of the cochlear endolymph. This finding seems to contradict any vital importance of these substances for the direct stimulatory function of the hair cells, if they are present in one part and absent in the other. The hair cells must be assumed to demand the same environmental conditions for their stimulation. However the conditions in the vestibular apparatus for transmission of mechanical energy would seem

to be favoured by a meshwork of polysaccharides. If they fill the canals in continuity with the cupulae, it seems probable that they are moved as an intimately bound unit in their responses to angular accelerations, whereas a gel-like conditions of the endolymph in the cochlea responding to the rapid fluctuations to tones and sound probably would be a functional disadvantage.

Finally from a morphological point of view this study aimed at showing the simplicity in the arrangement of the two main cell types of the specialized epithelium in the whole inner ear. The dark ion-exchanging and the light secretional cells are everywhere located in the closest vicinity to the sensory cell areas. The clearly separated dark and light cells in the primitive cochlea of the pigeon with their distinctly separated functions might therefore serve as a simple pattern of the more complicated stria vascularis in higher animals.

THE RADIOLOGIC DIAGNOSIS OF OTOSCLEROSIS

H Røvsing

From the Radiological Department University Hospital Copenhagen, Denmark

Tomography employing Philips Macrot's Polytome in the semi-axial and the axial-pyramidal projection allows tomographic demonstration of fenestral and retrofenestral otosclerosis, respectively. Examples of otosclerotic changes in the labyrinthine windows, the promontory and the fossula of the vestibular window are demonstrated. The tomographic difference between active and inactive otosclerosis is shown and the

pathological changes of the cochlea compatible with the diagnosis of retrofenestral otosclerosis are demonstrated along with some cases of re-impaired hearing following stapedectomy by the method of Schuknecht in which re-oblitration of the vestibular window or dislocation of the wire has been diagnosed tomographically.

THE IBSEN-MACKEPRANG COLLECTION
TOMOGRAPHY AND PHOTOGRAPHY

J Jensen and L. Hansen

From the Radiological Department, University Hospital, Copenhagen, Denmark

The Ibsen-Mackeprang Collection was created in the period from 1874 to 1897 and comprises 101 admirably prepared temporal bones from deaf children. Of the specimens 36 present abnormalities within the labyrinth. In 18 of these the changes must be regarded primarily as developmental anomalies. In the remaining 14, the changes consist of osseous obliterations, either of the entire labyrinth, or parts of it. In the specimens with obliteration, the origin of deafness

was postnatal in 14. In the remaining four the origin of deafness was unknown; in two the children were stated to be born deaf.

Nine specimens reveals Mondini malformation, i. hypoplasia of the axial skeleton of the cochlea, resulting in only 1 coil. In one of the temporal bones atresia of the posterior semicircular canal is present, and in two the internal acoustic meatus is malformed.

In the remaining 18 the changes consist of osseous obliteration, either of the entire labyrinth, or parts of it. In the specimens with obliteration, the origin of deafness

was postnatal in 14. In the remaining four the origin of deafness was unknown; in two the children were stated to be born deaf.

Nine specimens reveal Mondini malformation, i.e. a hypoplasia of the axial skeleton of the cochlea, resulting in only 1 coil. In one of the temporal bones epistasis of the posterior semicircular canal is present, and in two the internal acoustic meatus is malformed.

THE RADIOLOGIC DIAGNOSIS OF OTOSCLEROSIS

II Røvsing

From the Radiological Department University Hospital Copenhagen, Denmark

Tomography employing Phillips-Masiot's Polytome in the semi-axial and the axial pyramidal projection allows tomographic demonstration of fenestral and retrofenestral otosclerosis, respectively. Examples of otosclerotic changes in the labyrinthine windows, the promontory and the fossula of the vestibular window are demonstrated. The tomographic difference between active and inactive otosclerosis is shown, and the

pathological changes of the cochlea compatible with the diagnosis of retrofenestral otosclerosis are demonstrated along with some cases of re-impaired hearing following stapedectomy by the method of Schuknecht in which re-obiteration of the vestibular window or dislocation of the wire has been diagnosed tomographically.

THE IBSEN-MACKEPRANG COLLECTION
TOMOGRAPHY AND PHOTOGRAPHY

J. Jensen and L. Hansen

From the Radiological Department, University Hospital, Copenhagen, Denmark

The Ibsen-Mackeprang Collection was created in the period from 1824 to 1837 and comprises 101 admirably prepared temporal bones from deaf children. Of the specimens 36 present abnormalities within the labyrinth. In 18 of these, the changes must be regarded primarily as developmental anomalies. In the remaining 14, the changes consist of ossicon obliteration, either of the entire labyrinth, or parts of it. In the specimens with obliteration, the origin of deafness

was postnatal in 14. In the remaining four, the origin of deafness was unknown; in two the children were stated to be born deaf.

Nine specimens reveals Mondini malformation, i.e. a hypoplasia of the axial skeleton of the cochlea, resulting in only 1 coil. In one of the temporal bones epistasis of the posterior semicircular canal is present, and in two the internal acoustic meatus is malformed.

OTO-PATHOLOGICAL EXAMINATION OF OTOSCLEROSIS AND
NEURINOMATA OF THE ACOUSTIC NERVE

M. Balslev Jørgensen, P. Bretlau, U. Ebert and E. Hentzer

From the Oto-Pathological Laboratory, University Hospital, Copenhagen, Denmark

The exhibition from the oto-pathological laboratory demonstrates:

- 1 Different localisation and activity of the otosclerotic focus.
- 2 Lateral neurinomata of the acoustic nerve
 - a. localised in the meatus acousticus internus
 - rare cases localised inside the modiolus and the scala tympani.

THE PHYSIOLOGY OF THE EUSTACHIAN TUBE - FILM

S Ingelstedt

From the Department of Otolaryngology University Hospital Lund, Sweden

The normal tubal function is quantitatively evaluated on a film at varied controlled pressure changes inside and outside the middle-ear cavity. The methods for such determinations are based on recordings of the movements of the intact ear drum. The aim is to show that such measurements performed during the conditions defined give possibilities of determining the volume of the air filled ear space, the elastic properties of the tympanic membrane, the events during changing ambient pressure or during the act of opening the tube.

DISCUSSION

M Tos

Mucous Glands and Goblet Cells in the Eustachian Tube

I should like to call attention to the mucous elements in the Eustachian tube. It contains about 40 sero-mucous glands and numerous goblet cells in the epithelium. The secretion produced by these mucous elements passes into the tubal lumen. The role of these mucous elements in tubal function is still unknown. It might well be imagined that in catarrhal conditions hypersecretion of the mucous glands and of the goblet cells occurs, resulting in an increase of tenacious secretion in the tube. This may entail tubal stenosis without any thickening of the mucosa or other abnormalities. It might also be imagined that in chronic catarrhal conditions there would be an increase in the gland mass in the tube and an increased number of goblet cells as in the trachea and bronchi in chronic bronchitis. The tubal mucosa is similar to that of the nose and lower airways. Just as the mucous secretion in these

sites increases in catarrhal conditions, the same may also apply to the Eustachian tube. Now and then, rustling of secretion in the tube may be heard in Politzer's manoeuvre or during insufflation of air.

In the Glostrup Hospital, Copenhagen, we are studying the development, structure, and distribution of the mucous elements of the Eustachian tube. This is being done by whole-mount methods in which the entire tube is dissected free, presenting itself as a thin tube consisting of mucosa and submucosa (Fig. 1). The entire tube with the middle ear is then stained *in toto* by the PAS-Alcian blue whole mount method. The mucous glands manifest themselves as blue, branched structures, the gland mass in the submucosa and the excretory duct debouching into the tubal lumen (Fig. 1). The goblet cells stand out as intensely blue-stained, round spots in the epithelium.

The development of the glands starts at the pharyngeal end of the tube in the 13th week of pregnancy. The glandular primordia grow down into the submucosa where they undergo dichotomous division several times, forming tubules and acini. The glands are present only in the pharyngeal half of the tube, with the greatest density around the pharyngeal orifice.

The goblet cells start forming in the 14th week of pregnancy, also at the pharyngeal end whence they continue towards the middle ear. Throughout foetal life the density of the goblet cells is greater in the pharyngeal than in the tympanic half of the tube. At birth

Fig. 1 Eustachian tube from foetus aged 21 weeks. PAS-Alcian blue-stained whole-mount ($\times 35$). The tube is 4 mm in length and 0.5 mm in diameter. Several glands (arrows) are already quite widely branched and situated in the submucosa. In the epithelium, many dark patches which represent groups of goblet cells are visible. The goblet cells are densest in the pharyngeal half (P), but also continue towards the hypotympanum (H). In other parts of the middle ear (T) there are only few goblet cells.

and during infancy the density of the goblet cells has already reached a maximum.

The object of these studies is to elucidate the anatomy of the mucous elements and to determine the density of goblet cells in a normal series. This is to form the basis of quantitative studies of the mucous elements

in disease, such as acute otosuppuritis, adhesive otitis, and chronic otitis media.

U Stribula: In a few cases of adhesive otitis we have succeeded in maintaining the operatively created air-filled tympanum by permanent insufflation with water saturated air.

EUSTACHIAN TUBE FUNCTION ASSESSED WITH TYMPANOMETRY A NEW TESTING PROCEDURE IN EARS WITH INTACT TYMPANIC MEMBRANE

J Holmquist

*From the Department of Otolaryngology and the Laboratory of Audiology
Sahlgren's Hospital University Göteborg Sweden*

A testing procedure allowing rapid and physiological determination of the tubal function in ears with intact ear drum is introduced. Testing results in normal as well as pathological ears are presented and discussed. The procedure seems to objectivize tubal func-

tion disorders which we have previously been unable to determine in clinical routine

(Published in Acta Oto-Laryngologica, Vol. 68, p. 501 1969)

POSTURE AND EUSTACHIAN TUBE FUNCTION

H. Rundcrantz

From the Departments of Otolaryngology University Hospital, Lund, Sweden

The patency of the Eustachian tube is affected by the position of the body—a phenomenon observed particularly in patients with patulous tubes. The symptoms of acute otitis media often start at night when the patient has been in bed for some hours. These facts indicate that the horizontal body position may constitute a factor contributing to the development of acute or chronic otitis media. The ventilatory capacity of the Eustachian tube has been studied in different postures. The clinical consequences of postural effects on the Eustachian tube are discussed.

During upper respiratory infections some symptoms often begin or grow worse at night a few hours after the patient has gone to bed. All of us have certainly noticed decreased nasal patency in the recumbent position during a common cold. It is also a well-known clinical fact that the symptoms of acute otitis media often start at night, and that the symptoms are sometimes alleviated when the patient gets up.

About 100 years ago it was first shown (Lucas, 186 Hartmann, 1879) that different positions of the head and different postures affected the patency of the Eustachian tube. In his by now classical investigations on healthy persons and patients with patulous tubes, Perlman (1939) found that the air flow through the tube was always impaired in the recumbent position. Perlman thought that during sleep at night the Eustachian tube should be considered impermeable.

Impairment or interruption of the essential air contact between the middle-ear cavity and pharynx through the Eustachian tube during an upper respiratory infection contributes to

the development of acute or serous otitis media. The medical literature contains only stray comments on the increased frequency of symptoms at night, which are typical of acute otitis media, and the factors underlying the phenomenon have not been analyzed. Nor are they—as a rule—considered in connection with the treatment of the disease.

Problem

Adult man spends about 8 hours every night in the horizontal position, small children even more. Patients with common colds are often advised to go to bed for a couple of days to cure the illness. To what extent is the normally patent tube affected by a change in the body position from the vertical to the horizontal level? How is the tube in various postures affected if the patient suffers from an upper respiratory infection?

METHOD

Fig. 1 shows a middle-ear model. In the bony part of the ear canal (cc) a polyethylene catheter is inserted and fixed air-tight. The tympanic membrane is perforated. Special arrangements with an electric fan can produce a constant negative or positive intratympanic pressure (Pm) through the catheter. When the tube opens during deglutition, an air volume will pass through the tube and also through the catheter (Vt).

The walls of the middle-ear space are prin-

A testing procedure allowing rapid and physiological determination of the tubal function in ears with intact ear drum is introduced. Testing results in normal as well as pathological ears are presented and discussed. The procedure seems to objectivize tubal func-

tion disorders which we have previously been unable to determine in clinical routine.

(Published in Acta Oto-Laryngologica, Vol. 68, p. 501 1969)

of air passing through the Eustachian tube during deglutition during health and infection. The decrease of tubal patency during infection, seen already in the erect position, became very marked in the 20° position. In the recumbent position, none of the subjects could open their tubes at all. After 10 minutes in this position, the tubal function did not recover until after 10–35 minutes in the erect position.

CONCLUSIONS

In subjects with normal tubal function, a change in the body position from the erect to the horizontal level causes a decrease in tubal patency to one third of that in the erect position. In a position of 20° above the horizontal plane, the patency decreases to only two thirds. This phenomenon is proved to be caused by the hydrostatic venous capillary congestion of the mucosa of the middle ear and the Eustachian tube. During upper respiratory infections, this positional effect is much more pronounced, so that the tube seems to be occluded in a body position below 20° above the horizontal

Fig. 4. The mean values of Vt in different positions in five subjects during health and infection.

plane. A rapid development of atelectasis of the middle ear will take place, which paves the way for middle-ear disease.

It would therefore be logical to recommend patients with common colds, especially children with a history of recurrent acute or serous otitis media, to take up a position during bed rest of not less than 20° above the horizontal plane in order to prevent tubal occlusion. The same advice should be given in the postoperative period to patients submitted to tympanoplastic surgery.

Fig. 3. The percentual mean values and S.D. of Vt in different positions and during neck-vein compression in healthy subjects.

Fig. 1 The principal arrangement of measuring the air volumes passing through the Eustachian tube (V_t) and the changes in volume of the middle-ear space (ΔV_{muc}).

cipally rigid but changes in its volume (ΔV_{muc}) appear as the result of variations in the capillary venous engorgement in the tympanic mucosa. ΔV_{muc} also produces small air flows through the catheter which is connected to an electronic measuring device capable of recording V_t as well as ΔV_{muc} with high accuracy expressed in terms of μl .

Sixteen persons with dry central perforations of the tympanic membrane were investigated. All of these could easily equilibrate negative and positive intratympanic pressures of 2 cm H₂O. In the investigation constant positive pressures of 2 or 4 cm H₂O were used. The subjects were asked to swallow once a minute during 10 minutes in different body positions. V_t was recorded on every deglutition, ΔV_{muc}

was recorded on every change in posture. The positions investigated were sitting erect, reclining 30° and 20° above the horizontal plane, and finally lying down horizontally.

RESULTS

Fig. 2 shows the results in one patient. The closer to the horizontal plane the subject was placed the more did V_t decrease. ΔV_{muc} , the volume change in the middle-ear space due to different capillary venous engorgement, was also proportional to the degree of the change in body position. Jonson & Runderantz (1969) made catheterizations and pressure recordings inside the bulb of the internal jugular veins of healthy individuals. In the sitting position the pressure was nearly zero. When the body position was changed towards the horizontal level, the venous pressure began to increase at the angle of 20° and in the horizontal position it was about 10 cm H₂O. This pressure was directly proportional to the level between the right auricle of the heart and the bulb. The same venous pressure could be produced in the sitting position if a tourniquet was applied round the neck and inflated to 35 cm H₂O. Such a venous compression also caused a decrease of V_t as seen in Fig. 2.

The mean values of the air volumes passing through the Eustachian tubes in different positions and during neck vein compression were calculated for the entire series. The values were expressed as the percentage of V_t in the sitting position (Fig. 3). Reclining 30° above the horizontal plane caused a reduction of tubal patency to 73%. In the 20° position the values decreased to 64% and in the horizontal position the patency of the tube was only 38% of the mean value in the sitting position. During neck vein compression the tubal patency was reduced to 44%.

Five of the patients fell ill with upper respiratory infections in the course of the investigation and could be re-examined during the infection. There was, however, no signs of middle ear infection. Fig. 4 shows the mean volumes

Fig. 2 V_t and ΔV_{muc} in one subject in different positions and during neck vein compression (Pnech 35 cm H₂O).

Very likely the type of patulous tube condition that appears during pregnancy and with the use of preventive pills (Allen, 1967) is also due to a mucous membrane affection.

The extraluminal factors include changes in muscles, cartilage and other tissues around the lumen of the Eustachian tube. Ostmann (1893) studied how atrophy near the tube could affect its patency. It is also well known that loss of weight with reduction of fat and subsequent reduced tissue pressure can give rise to a patulous tube condition.

After operations on the epipharynx or near the Eustachian tube a patulous condition may arise because of adhesions directly or indirectly affecting the mechanism of opening and closing the Eustachian tube. Radiological treatment of epipharynx tumours may also result in a patulous tube owing to postradiological changes.

It was shown by Politzer (1861) and later by Rich (1920) that the Eustachian tube is opened by the tensor veli palatini muscle, probably with the aid of the levator veli palatini muscle. Occasionally this muscle mechanism can be systematically trained, so that the Eustachian tube may be opened voluntarily (Wernli, 1964).

The patulous tube may also be due to a combination of luminal and extraluminal factors. An example of this can be seen in cases with chronic otitis. Zöbner (1942) and Flisberg (1966) showed that the condition may be more common in patients with chronic otitis. The reason for this is likely to be a combination of mucous membrane changes and fibrotic changes in the tissues around the tubal lumen caused by the chronic infective condition. Perlman (1939) proved that a patulous tube could arise after retrogasserian neurectomy performed to relieve trigeminal neuralgia. He thought that a lack of tones of the muscles that affect the Eustachian tube (tensor veli palatini muscle) and are supplied by the fifth nerve is the principal factor in producing the clinical entity. However Handl (1959) and Flisberg (1966) expressed the view that a certain influence on the mucous membrane may also contribute to the patulous state of the Eustachian tube after this operation.

PRESENT INVESTIGATIONS

Material

A retrospective investigation was made covering all patients with a diagnosis of patulous tube in the ENT Department, Lund, since 1964. A total of 90 cases of unquestionable patulous tube condition were found, verified by Eustachian tube function test. Fifty-three of these cases, i.e. 63% were women. There were five patients in the series who had been operated on with retrogasserian neurectomy because of trigeminal neuralgia, six had chronic otitis media, and six women stated that they used oral contraceptive preparations. Questionnaires were sent to all patients in whom the condition had been diagnosed during 1967 and 1968 (50 patients) inquiring about their symptoms.

Method

To elucidate the mechanisms and solve the problem why the symptoms sometimes disappear (for example, in the recumbent position, a further investigation was made in some of the patients. At nasal respiration, recordings were made of the pressure changes in the nose and the middle ear across the intact ear drum in different body positions. The equipment used has previously been described in detail by Ingelstedt *et al* (1967).

Results

Answers were given by 34 of the 50 patients asked. In five answers, spontaneous improvement of all symptoms was stated. The improvement had followed a certain weight increase or the end of pregnancy. There was no chronic otitis media or operatively induced patulous tube among the patients. Table 1 gives the frequency of positive symptoms in the remaining 29 patients. The most common symptom—feeling of deadness in the ear—was mentioned by 19 of the patients. This symptom was felt in the erect position, but only one patient had trouble also at night or when lying down.

MIDDLE EAR MECHANICS IN PATULOUS TUBE CASES

K. Flisberg and S. Ingelstedt

From the Department of Otolaryngology University Hospital Lund Sweden

Over a 5-year period 90 cases with patulous tube conditions verified by Eustachian tube function tests were found at the ENT Department of Lund. Sixty-three per cent of these were women. By questioning the various symptoms could be evaluated. To elucidate the factors which might relieve the symptoms, 11 simultaneous pressure recordings in nose and middle ear were made in some of the patients. Two factors seemed to relieve the symptoms: an increase of the hydrostatic pressure in the head and a relative under pressure in the middle ear.

The patulous Eustachian tube was described for the first time 1864 by Schwartze who observed that a scarred ear drum moved synchronously with the breathing. A more complete report of the condition was given by Jago (1867). He had himself had right sided patulous tube trouble. Not until Jago increased in weight by $\frac{1}{2}$ of his original weight did the symptoms disappear. The same happened now and even earlier "for several hours after a hearty meal". Except for occasional reports, little attention was paid to the patulous tube condition until the 1930's when it was discussed by Pitman (1929), Zöllner (1937), Shambaugh (1938) and Perlman (1939). For some years, several authors have called attention to the patulous tube condition and also discussed aetiology, symptomatology and treatment, inter alia Metz (1953), Moore & Miller (1961), Miller (1961), Pulec & Simonton (1964) and Allen (1967).

Symptoms

The symptoms often seem to be paradoxical, as many of them resemble the symptoms seen in obstruction of the Eustachian tube. This certainly contributes to a common tendency to

overlook the condition. The patulous tube has actually proved to be considerably more common than has previously been realized.

The symptoms are

- 1 Feeling of head as "in an empty barrel" (feeling of deafness in ear)
- 2 Autophony
- 3 Tinnitus
- 4 Feeling of one's own breathing in the ear
- 5 The symptoms may be aggravated by exercise, fatigue and nervousness.
- 6 The symptoms may be aggravated by loss of weight or start after loss of weight.
- 7 The symptoms may be relieved by upper respiratory infection.
- 8 The symptoms may be relieved by the horizontal position.
- 9 The symptoms may be relieved by sharp "sniffing"

Aetiology

Theoretically the condition of the patulous tube state may be caused by luminal factors, extraluminal factors or a combination of both.

The luminal factors include different types of mucous membrane changes. These factors probably play an important role in the regulation of the patency of the tube. In most cases, the simple procedure to ask the patient to lie down eliminates patulous tube trouble. This is due to the increasing degree of filling of the veins and lymphatic vessels owing to the higher hydrostatic pressure in the head in the horizontal position.

Fig. 3. Pressure recordings in the same case as in Fig. 1 and 2. The patient placed horizontally. At the arrow the Eustachian tube has closed - level of the middle-ear pressure curve.

inspiration phase when the tendency of the Eustachian tube to close, because of the hydrostatic factor was increased by the pressure relations in nose and ear causing a sucking effect. When the Eustachian tube was closed, this could be recorded as a levelling of the middle-ear pressure curve. The pressure in the middle ear was then always negative.

DISCUSSION

The patulous tube has previously been considered a rather unusual condition. In recent years, interest has more and more tended to focus on the clinical entity. This is probably the reason why an increasing number of cases have been reported.

Of special interest are the patulous cases with follow retrogasserian neurectomy. According to Perlman (1939), this type of patulous tube is chiefly caused by extraluminal factors, "lack of muscle forces". An objection to this theory is the fact that the Eustachian tube is opened by the very muscle which at this operation is in danger of losing its innervation. However, according to Graves & Edwards (1944), the sensory innervation to the pharyngeal orifice of the Eustachian tube can also be innervated by the trigeminal nerve (normally by the glossopharyngeal nerve). After retrogasserian neurectomy an atrophy of the mucous membrane of the same side of the nose may be combined with a patulous tube. This would then be due to trophic disturbances of the mucous membrane of the Eustachian tube.

During the medication of oral contraceptive

preparations there is an increase in the level of oestrogen in the blood (just as in pregnancy). The oestrogen affects the mucous membrane of the nose and epipharynx either directly or indirectly via the pituitary gland (Schiff, 1959). It could be mentioned by way of comparison that oestrogen not only affects the thickness of the mucous membrane of the genital tract, but also that the secretion from the cervix uteri becomes thinner and the cervix dilated due to this hormonal action. The hormonal influence seems to cause a patulous tube condition as a side effect in certain cases.

During the investigation of a patient with a patulous tube in different body positions it was observed that the Eustachian tube varied with body position as well as with pressure relations in the nose and middle ear. A horizontal body position always closed the Eustachian tube because of the increased hydrostatic pressure in the mucous membrane of the head. The same tendency was observed when a relative under pressure in the middle ear was built up. Such a pressure relation tends to close the lumen of the Eustachian tube. This type of pressure relation appears at inspiration. Patients with patulous tube use this phenomenon to get rid of the symptoms by performing a so-called "sniffing or reverse Valsalva manoeuvre". Conversely a higher pressure in the nose than in the middle ear tends to dilate the Eustachian tube as previously demonstrated by Flisberg (1966). In the study of normal individuals during tubal function test it could be observed that the Eustachian tube was periodically open. This often happens when the patient has performed Valsalva's manoeuvre, during which the Eustachian tube had been opened and dilated. Probably the same takes place now and then normally and the state of patulous tube can then hardly be regarded as pathological.

The symptoms of patients with patulous tubes might be curious as well as unpleasant. Often the patients' trouble has, furthermore, been neglected at one or several examinations. When the diagnosis is established, most patients are content with the information that it is a quite

Figs. 1-3 show the pressure changes which could be recorded in a patient with a patulous tube in different body positions.

In Fig. 1 with a patient in the erect position the pressure changes in the nose and middle ear practically agree with only a small delay of the middle-ear pressure in relation to the pressure in the rhinopharynx. At expiration (a) there were the same pressure in the nose and the middle ear (+ 1.8 cm H₂O). Because of this positive

Fig. 1 Pressure recordings in nose (P_n) and middle ear (P_m) at nasal respiration in a patulous tube case (woman, 18 years old) in the erect position. At (a) expiration (b) zero level at change between phases of inspiration and expiration (c) zero level change between phases of expiration and inspiration (d) inspiration. A brief closing of the Eustachian tube is seen as a levelling of the middle-ear pressure curve

Fig. 2. Pressure recordings in the same case as in Fig. 1. Upper curve: the patient placed in the erect position. Lower curve: the patient placed with head 25 above the horizontal plane.

pressure the ear drum bulged outwards. At the stage between the inspiration and expiration phases (b) the pressure in the nose was positive—here + 1 cm H₂O—when the pressure in the middle ear was zero which meant a normal ear-drum position at that very point. This pressure relation gave a slight dilatation of the Eustachian tube, which was also the case at (a) with positive pressures in nose as well as middle ear. When the pressure in the nose was lower than in the middle ear which was the case at (c) and (d) the reverse took place i.e. a tendency of the Eustachian tube to become narrower or to close. In fact, the tube closed at (d) which could be seen as a straight line in the middle-ear pressure curve during the maximum of inspiration.

In Fig. 2 the upper curve shows the pressure changes when the patient was in the erect position. Lower curve the patient was placed with his head in a position 25° above the horizontal plane according to the findings of Rundcrantz (1969). A moderate delay of the middle-ear pressure was the result. This delay was an expression of the tendency of the Eustachian tube to close because of the increased pressure in the mucous membrane vessels. The delay was seen as a time displacement of the middle-ear pressure curve on the abscissa.

In Fig. 3 the patient was placed horizontally. Then a marked delay of the middle-ear pressure could be seen up to the closing of the Eustachian tube. This closing always took place at an

Fig. 3. Pressure recordings in the same case as in Fig. 1 and 2. The patient placed horizontally. At the arrow the Eustachian tube has closed - level of the middle-ear pressure curve.

inspiration phase when the tendency of the Eustachian tube to close, because of the hydrostatic factor was increased by the pressure relations in nose and ear causing a sucking effect. When the Eustachian tube was closed, this could be recorded as a levelling of the middle ear pressure curve. The pressure in the middle ear was then always negative.

DISCUSSION

The patulous tube has previously been considered a rather unusual condition. In recent years, interest has more and more tended to focus on the clinical entity. This is probably the reason why an increasing number of cases have been reported.

Of special interest are the patulous cases with follow retrogasserian neurectomy. According to Perlman (1939) this type of patulous tube is chiefly caused by extraluminal factors, "lack of muscle tone". An objection to this theory is the fact that the Eustachian tube is opened by the very muscle which at this operation is in danger of losing its innervation. However according to Groves & Edwards (1944) the sensory innervation to the pharyngeal orifice of the Eustachian tube can also be innervated by the trigeminal nerve (normally by the glossopharyngeal nerve). After retrogasserian neurectomy an atrophy of the mucous membrane of the same side of the nose may be combined with a patulous tube. This would then be due to trophic disturbances of the mucous membrane of the Eustachian tube.

During the medication of oral contraceptive

preparations there is an increase in the level of oestrogen in the blood (just as in pregnancy). The oestrogen affects the mucous membrane of the nose and epipharynx either directly or indirectly via the pituitary gland (Schiff 1959). It could be mentioned by way of comparison that oestrogen not only affects the thickness of the mucous membrane of the genital tract, but also that the secretion from the cervix uteri becomes thinner and the cervix dilated due to this hormonal action. The hormonal influence seems to cause a patulous tube condition as a side effect in certain cases.

During the investigation of a patient with a patulous tube in different body positions it was observed that the Eustachian tube varied with body position as well as with pressure relations in the nose and middle ear. A horizontal body position always closed the Eustachian tube because of the increased hydrostatic pressure in the mucous membrane of the head. The same tendency was observed when a relative under pressure in the middle ear was built up. Such a pressure relation tends to close the lumen of the Eustachian tube. This type of pressure relation appears at inspiration. Patients with patulous tube use this phenomenon to get rid of the symptoms by performing a so-called "sniffing" or reverse Valsalva manoeuvre. Conversely a higher pressure in the nose than in the middle ear tends to dilate the Eustachian tube as previously demonstrated by Flisberg (1966). In the study of normal individuals during tubal function test it could be observed that the Eustachian tube was periodically open. This often happens when the patient has performed Valsalva's manoeuvre during which the Eustachian tube had been opened and dilated. Probably the same takes place now and then normally and the state of patulous tube can then hardly be regarded as pathological.

The symptoms of patients with patulous tubes might be curious as well as unpleasant. Often the patients' trouble has, furthermore, been neglected at one or several examinations. When the diagnosis is established, most patients are content with the information that it is a quite

Figs. 1-3 show the pressure changes which could be recorded in a patient with a patulous tube in different body positions.

In Fig. 1 with a patient in the erect position the pressure changes in the nose and middle ear practically agree with only a small delay of the middle-ear pressure in relation to the pressure in the rhinopharynx. At expiration (a) there were the same pressure in the nose and the middle ear (+1.8 cm H₂O). Because of this positive

Fig. 1 Pressure recordings in nose (P_n) and middle ear (P_m) at nasal respiration in a patulous tube case (woman, 18 years old) in the erect position.

At (a) expiration (b) zero level at change between phases of inspiration and expiration (c) zero level change between phases of expiration and inspiration (d) inspiration. A brief closing of the Eustachian tube is seen as a levelling of the middle-ear pressure curve.

Fig. 2 Pressure recordings in the same case as in Fig. 1. Upper curve: the patient placed in the erect position. Lower curve: the patient placed with head 25° above the horizontal plane.

pressure the ear drum bulged outwards. At the stage between the inspiration and expiration phases (b) the pressure in the nose was positive—here +1 cm H₂O—when the pressure in the middle ear was zero which meant a normal ear-drum position at that very point. This pressure relation gave a slight dilatation of the Eustachian tube which was also the case at (a) with positive pressures in nose as well as middle ear. When the pressure in the nose was lower than in the middle ear which was the case at (c) and (d) the reverse took place i.e. a tendency of the Eustachian tube to become narrower or to close. In fact, the tube closed at (d) which could be seen as a straight line in the middle-ear pressure curve during the maximum of inspiration.

In Fig. 2 the upper curve shows the pressure changes when the patient was in the erect position. Lower curve: the patient was placed with his head in a position 25° above the horizontal plane according to the findings of Rundcrantz (1969). A moderate delay of the middle-ear pressure was the result. This delay was an expression of the tendency of the Eustachian tube to close because of the increased pressure in the mucous membrane vessels. The delay was seen as a time displacement of the middle ear pressure curve on the abscissa.

In Fig. 3 the patient was placed horizontally. Then a marked delay of the middle-ear pressure could be seen up to the closing of the Eustachian tube. This closing always took place at an

TUBAL FUNCTION IN PATIENTS WITH CHRONIC SECRETORY OTITIS MEDIA

O Westergaard

From the Department of Otolaryngology University Hospital Copenhagen, Denmark

Tubulation of the middle ear in patients with chronic secretory otitis offers an opportunity to evaluate the tubal function by means of aspiration by the method of Flisberg. The tubal function was followed in 18 patients by this method for 6 months and was found to be definitely inferior to normal values as given by Holmquist.

The aetiology of chronic secretory otitis media is still under discussion. Most investigators agree that the tubal function is of major importance, which is also implied by the fact that removal of adenoids is recommended as the first procedure in the treatment of this condition.

This report presents an attempt to evaluate the tubal function in children with secretory otitis media of long duration. There are a number of methods by which the tubal function can be determined. The so-called indirect methods are widely used, but can only be applied when the tympanic membrane is intact and the middle-ear space contains air. Flisberg *et al* (1962) developed a very promising method, the so-called aspiration method, which, however, requires that there is a perforation of the tympanic membrane.

They applied a negative pressure in the ear canal, and the criterion was how far this pressure would be reduced by repeated swallowing, or in other words, the minimum pressure gradient between the nasopharynx and the middle ear that would still produce an opening of the tube during swallowing. Holmquist (1968) used this method in a number of patients with perforations of the eardrum and correlated the findings to the clinical results

obtained by myringoplastic operations. One group of patients were able to reduce the ear canal pressure to -100 mm water or less. Here the operation was a complete success in 75 % against only in 12 % of the patients in whom the tubal function was poorer.

This method appears to be ideally suited for measuring the tubal function in patients with chronic secretory otitis media which had necessitated a tubulation of the tympanic membrane by the method of Armstrong (1954).

The examination was conducted as follows: Pressures were applied by means of the Madsen ZO 70 impedance apparatus, which contains a pump system and will register pressures within a range of ± 400 mm water. Fitting of the insert to the ear canal was performed in the usual way by means of Medrescotype plastic tips. We first applied a slowly increasing positive pressure. Under normal circumstances this will cause an opening of the Eustachian tube in a passive way when a pressure of $150-300$ mm water is reached. If no such opening was obtained within the measuring range of 400 mm pressure, the patient was requested to swallow some water in order to provoke an active opening. If the pressure following the opening of the tube did not reach a value close to zero it was attempted to cause a further reduction by repeated swallowing. This procedure served to prove that the drainage tube functioned, and at the same time to measure how large a positive gradient was needed to cause an opening of the tube.

We then proceeded to the application of

harmless condition. The therapeutic procedures which are available and necessary are in general extremely simple.

DISCUSSION

P Berdal Tuba aperta does not always represent a pathological condition. My own tubes have been patulous for more than 20 years without signs other than movements corresponding to the respiratory phases.

O Meurman How many cases with cut trigeminal in the middle ear after such an operation are likely to occur. I have seen a case of chronic serous otitis media which developed after operation for trigeminal neuralgia.

A Flisberg (Reply to Berdal) There are probably several individuals who have patulous tubes, either constantly or periodically. Some of them do not notice the condition in a more scientific way. However, some individuals, who are sensitive, really suffer from the symptoms, and this group should obviously be treated. There is another group of individuals who can voluntarily open the Eustachian tube. This capacity is often found among pilots who because of their work are exposed to rapid and great pressure changes and have to learn how to equilibrate.

(Reply to Meurman) Among the 90 patients with patulous tube there were five who had been subjected to retrogasserian neurectomy because of trigeminal neuralgia. The question whether tuba aperta or tuba clausa (obstructed tube) will develop postoperatively depends on the operative procedure and the part of the trigeminal nerve that has been damaged. If the sensory innervation of the lower part of the Eustachian tube is through the trigeminal nerve and the motor innervation to the opening muscles is intact, retrogasserian neurectomy may result in atrophy of the mucous membrane with a patulous tube. If however the motor innervation to the tensor veli palatini muscle is damaged in the operation, it is possible that this will result in a closed Eustachian tube. If the mucous membrane affection does not predominate, there are undoubtedly cases with serous otitis or chronic otitis media after this operation.

EUSTACHIAN TUBE PATENCY IN CHRONIC EARS PRE-OPERATIVE EVALUATION CORRELATED TO POSTOPERATIVE RESULTS

A. Palva and J. Kärjä

From the Department of Otolaryngology, University of Oulu, Finland

Eustachian-tube patency was assessed with Bortnick technique in 120 chronic ears. The positive test correlated reasonably well with good postoperative results in the normal tympanum and in cases of mild tympanic pathology. In general, the otomicroscopic result as found to provide a more reliable basis for estimation of the prognosis of tympanoplasty if the formation of adhesions during the primary healing period is prevented, the function of the Eustachian tube can postoperatively be restored, making an aerated tympanum possible.

Proper function of the Eustachian tube is one of the main requirements for successful tympanic reconstruction, and testing the patency of the tube is at present one of the routine pre-operative examinations. A number of tests have been presented from which quantitative information is gained on the function of the Eustachian tube (Flisberg *et al.*, 1963; Miller, 1965; Bortnick, 1966; Siedentop *et al.*, 1968). Only a few studies (Hosse & Sheehy, 1963; Holmgvist, 1968; Siedentop *et al.*, 1968) have dealt with the real significance of pre-operative Eustachian-tube function tests, i.e. with their correlation to postoperative results. Much additional clinical information on this subject is required.

MATERIAL AND METHODS

The series consisted of 120 chronic ears. In 25 cases, simple myringoplasty was performed, the others were subjected to radical mastoidectomy with various types of tympanoplasty (Palva *et al.*, 1967; Palva, T. 1968, 1969). The postoperative observation time varies from one to

three years. The hearing result was considered successful if the practically useful level 0-40 dB (ISO-standard, Davis & Krantz, 1964) was achieved and maintained.

The pre-operative measurement of Eustachian-tube function was as follows (Bortnick, 1966): the external auditory canal was fitted airtight with a No 12 Foley catheter connected to a manometer. The pressure in the system could be changed from +30 cm H₂O to -30 cm H₂O. The minimum positive pressure necessary to open the Eustachian tube passively was first measured. Thereafter a negative pressure of -30 cm H₂O was established in the middle ear and the possible equalization of the pressure during ten subsequent swallows was observed. The test was considered to indicate Eustachian-tube patency and thus to be positive if a pressure of 30 cm H₂O or less opened the tube and/or if the decrease in negative pressure after swallowing exceeded 5 cm H₂O.

RESULTS

Myringoplasty

All 25 myringoplasty ears had a dry central perforation. The tympanic mucosa appeared normal when inspected with an otomicroscope. Pre-operative testing of Eustachian-tube function was positive in 17 and negative in eight ears. The results are illustrated in Fig. 1. The single failure in healing, and consequently in hearing gain, was due to postoperative infection.

negative pressures. It was first ascertained if a pressure of -200 mm would give an opening during swallowing. The examination was repeated with pressures of -300 and -400 mm water.

The amount of air that passes through the tube during such an active opening is small and it is important that the total volume of the measuring system is not too large, as otherwise many swallowing actions may be needed to reach the final value. In the apparatus used the pump system together with the tubes has a capacity around 1.5 ml which proved to be adequate.

We examined a total of 18 children. Their ages ranged from 3 to 15 years. The proved duration of the condition 2 months to 7 years. The first examination was performed on the first postoperative day and then at regular intervals up to 6 months. The results show rather surprisingly that none of the patients were able to reduce negative pressures at all at any time during the follow up.

In the immediate postoperative period 54 % were able to reduce positive pressures to a level of 10 cm water. At the end of the follow up, 76 % would achieve this level but here the number of subjects is very small 45 % (11) of the drainage tubes were extruded in the observation period most of them during the fifth or sixth month.

In seven patients this necessitated retubulation. In three patients, the middle-ear pressure

was pathologically negative, but so far without recurrence of secretion. One patient did not return for follow-up.

Conclusions

The tubal function in a group of patients with chronic secretory otitis media measured according to the aspiration method was very poor. The level to which positive pressures could be reduced indicated a tendency to very slight improvement during the observation period but without exceptions the function remained very poor.

Fig. 3 Results of tympanoplasty in 30 cases of tympanoplasty in ears with diseased tympanic mucosa and negative test of Eustachian-tube function. The cases are related to the method used for preventing tympanic adhesions. The shaded area indicates failure in tympanoplasty

membranous scar near the tubal isthmus, each in one case. In 18 cases (31 %) the cause of the negative tubal function test could be found neither on otomicroscopy nor at operation.

In the group of 23 cases with a normal tympanic mucosa, the tympanoplasty was successful in 19 (83 %). The causes of failure were: one serous labyrinthitis pre-operatively, one postoperative infection leading to perforation of the tympanic membrane, one partially adhesive tympanum and one case of deterioration of hearing one year after operation without apparent cause.

When the tympanic mucosa was diseased and the Eustachian-tube function test negative, the tympanoplasty was successful in 17 cases (49 %). Causes of failures were: adhesive tympanum in seven, perforation of the tympanic membrane in six, two of whom showed recurrent discharge. In five cases, no reconstruction was made: two cases had a labyrinthine fistula, and three an extremely severe tympanic pathology.

If the tympanic mucosa had to be removed, the development of an adhesive tympanum was very common if no special method was used for its prevention (Palva *et al.* 1968; Palva, A. 1968). Thus, in the present series, Salastic sheeting or paraffin filling was utilized in 30 cases. Fig. 3 shows the results of tympanoplasty in cases of diseased tympanic mucosa with negative result in the Eustachian-tube function test, as related to the method used for prevention of adhesions. It is seen that, using a careful operation technique and an appropriate method, the development of an adhesive tympanum can be noticeably reduced. This finding

indicates the restoration of Eustachian-tube function after healing of infection.

DISCUSSION

A positive Eustachian-tube function test correlates best with the postoperative results in cases of normal tympanum or of mild tympanic pathology. However an otomicroscopic examination clearly gives more reliable information on the success of a future tympanoplasty. This fact is seen from Fig. 2, in which the cases with normal tympanic mucosa were equally successful (77 % and 83 %) in spite of differences in the Eustachian-tube function tests. The same applies to the myringoplasty cases. Thus, we wish to stress the statement of House & Sheehy (1963) that it is the otomicroscopic evaluation that tells us much about the Eustachian-tube function in most cases.

There are various causes of failure of tympanoplasty. The most uniform group is the development of an adhesive tympanum, which may often suggest hypoventilation of the Eustachian-tube. However a very important part is played by the adhesions forming between the reconstructed tympanic membrane and the bare promontory bone during the immediate postoperative period in spite of Valsalva manoeuvring and Politzerization. This is clearly evident from our previous experience (Palva *et al.* 1968; Palva, A. 1968; Palva, T. 1969) and also from Fig. 3. Similarly a situation familiar to every operating otologist can appear postoperatively later on, some months after tympanoplasty the posterior part of the tympanum is adhesive, while in the anterior corner an aerated small tympanum may be discovered as evidence of the restoration of Eustachian-tube function. If the development of adhesions can be effectively controlled during the healing period, the restoration of Eustachian-tube function permits adequate ventilation of an open tympanic cavity.

In the light of these facts we cannot agree with the statement that a negative result in testing for Eustachian-tube function is a con-

TEST POSITIVE

TEST NEGATIVE

Fig 1 Results of pre-operative Eustachian tube function tests and tympanoplasty in 25 cases of myringoplasty. The shadowed area indicates failure in tympanoplasty.

Radical Mastoidectomy

For examination of the results of tympanoplasty in these patients the condition of the tympanic mucosa must be evaluated. We have classified the patients as follows: those having a normal or moderately thickened mucosa and those in whom the mucosa was granulating, contained squamous epithelium or was otherwise in a condition necessitating removal.

Eustachian Tube Function Test Positive

A positive Eustachian tube function test was found in 37 (39 %) of the 95 ears with radical mastoidectomy. In 22 of these for both positive and negative pressure. In 11 ears, patency was obtained only with negative pressure. In four cases, the negative pressure showed no tendency to equalization although the positive pressure test opened the tube.

Fig. 2 shows in its upper part the 37 cases with a positive Eustachian tube function test related to the state of the tympanic mucosa. The majority of cases in this group (31) had normal tympanic mucosa. In seven of these ears (23 %) tympanoplasty was not successful, the causes of failure being otosclerotic stapes fixation in two, labyrinthine fistula in two, and on whom no tympanoplasty was performed.

Fig 2. Results of pre-operative Eustachian tube function test and tympanoplasty in 95 cases of radical mastoidectomy. The cases are grouped according to the state of the tympanic mucosa. The shadowed area indicates failure in tympanoplasty.

and the development of an adhesive tympanum in three.

Among six patients in whom the tympanic mucosa was diseased there were four failures: one tympanosclerotic fixation of the ossicular chain, one malposition of the prosthesis in an aerated tympanum, one labyrinthine fistula with no ossicular reconstruction and one postoperative development of adhesive tympanum. Thus, of the 11 failures in this group, four were caused by the development of an adhesive tympanum. In two of these the Eustachian tube did not open at a positive pressure while with negative pressure the equalization was not complete. The other two ears showed a completely positive test, one of these being a case of diseased mucosa. A sign of relatively slight tympanic pathology in these cases with positive Eustachian tube function test was that the ossicular chain was intact in nine cases (24 %) and the stapedial crura were missing in only seven cases (19 %).

Eustachian Tube Function Test Negative

The test for Eustachian tube function was negative in 58 cases (61 %). These are analysed according to the state of the tympanic mucosa in the lower part of Fig 2. The majority of cases (35 or 60 %) in this category showed a grossly diseased middle-ear mucosa. The severity of tympanic pathology is also indicated by the fact that there were only nine cases (15 %) with an intact ossicular chain, and in 20 cases (35 %) the stapedial crura were absent.

The cause of the negative test result was discovered on otomicroscopy in 40 cases (69 %). In 11 the perforation opened into a cholesteatoma sac, and there was no connection from the ear canal to the tympanum, while the possible existence of an aerated tympanum could be assumed on inspection with the pneumatic speculum. In 14 cases, granulation tissue occluded the tubal ostium. 10 ears showed a clearly adhesive tympanum and two a bony occlusion. Additional causes were: a metallic foreign body, a tympanic membrane, and a

CHRONIC OBSTRUCTION OF THE EUSTACHIAN TUBE TREATED WITH A TYMPANO-MAXILLARY SHUNT

B. Drettner and L. Ekvall

From the Department of Otolaryngology, University Hospital, Uppsala, Sweden

Four patients with complete obstruction of the Eustachian tube were treated by the application of a shunt between the middle ear and the maxillary sinus with preservation of an intact tympanic membrane. Good results of the middle ear and improved hearing were obtained in all patients. No complications have occurred, but one patient has otosclerosis. Slipping of the tube in one patient necessitated re-operation. Pressure recordings performed from 2 months to 2 years postoperatively showed that air was passing up to the middle ear on forced breathing or the Valsalva manoeuvre in all patients.

One problem in middle-ear surgery which has not yet been solved is the management of an obstruction of the Eustachian tube, where the only technique currently available is to fenestrate the tympanic membrane either through an indwelling tube or a natural perforation (Armstrong, 1954; Austin, 1969).

A new method for restoring the ventilation of the middle ear in cases with chronic obstruction of the Eustachian tube has been developed and tested over a period of 2 1/2 years (Drettner and Ekvall, 1967, 1969).

METHOD

The principle in this method is to create a permanent communication between the middle ear and the maxillary sinus by means of a silicone rubber tube. The tympano-maxillary shunt (TMS) runs from the anterior part of the middle ear in a groove in the bony men-

tus under the nasal skin and curves anteriorly in the lateral part of the meatus, to pass above and medial to the zygomatic root and medial to the muscular process of the mandible to the postero-lateral wall of the maxillary sinus, which it enters through a hole.

The silicone rubber tube, which is flexible and radio-opaque, has an internal diameter of 1.2 mm and an external diameter of 2.5 mm. It has several small side holes at the end, which is introduced into the maxillary sinus. It is the same tube which has been employed for many years by neurosurgeons in shunt operations for hydrocephalus. When used in the latter operations, the extreme tip of the tube is closed, but for tympano-maxillary shunts this tip is usually cut.

The TMS is applied under general anaesthesia. A retro-auricular incision is extended along the antero-superior attachment of the pinna. The nasal skin and the auricular fibrous are elevated from the bony canal, exposing the posterior superior and anterior parts of the middle ear. The tympanic membrane is also elevated from the malleus, but is still attached to the umbo. The anterior ligament of the malleus is cut. A groove is drilled in the anterior part of the bony meatus from the middle ear out to the medial aspect of the zygomatic root, and the capsule of the temporo-mandibular joint is exposed. A blunt elevator is introduced medial to the zygoma towards the postero-lateral wall of the maxillary sinus pointing to the midline of the incisors of the upper jaw

This work is supported by the Swedish Medical Research Council, Project No. 849-17X 749-04C

tra indication to tympanoplasty. The reason for failure, in very many cases, lies elsewhere than in the hypofunction of the Eustachian tube. For a successful tympanoplasty the most important points are the state of the tympanum as evaluated with the otomicroscope and appropriate measures in ossiculoplasty and in the prevention of adhesions.

tube was left in place for one month and used for inflation of the middle ear. All patients had complete obstruction of the Eustachian tube as determined by objective tests of the tubal function also during Valsalva and Politzer manoeuvres, and pressures up to 60 cm H₂O in the nasopharynx did not overcome the resistance.

Transudate was present in the middle ear in all cases at operation. The patient who had had an adhesive tympanic membrane treated with lysis and silastic sheeting during a previous operation, had no adhesions in the middle ear at the application of the shunt, but the tympanic orifice of the Eustachian tube was anatomically completely obstructed.

There were no complications during the operations and healing was excellent (Table 2). The tympanic membranes remained intact. The meatal skin became closely attached to the tube. None of the patients has had acute otitis or sinusitis since the operation. The observation periods since the application of TMS are now from 4 months to 2 1/2 years.

The aeration of the middle ear has been excellent except in one patient, in whom there was a recurrence of transudate after 4 months due to slipping of the tube outside the middle ear cavity but it still lay under the meatal skin. No suture to the temporo-mandibular joint capsule had been used in this patient, who was subjected to re-operation 11 months after the first application of TMS, and the tube, which was still patent, was only pushed a few

Fig. 1 Hearing results in four patients treated with application of tympano-mastoid shunt.

millimetres down in the middle ear and sutured to the joint capsule.

Re-operation was also performed in the patient first operated on, because of fixation of the meatus to the lateral attic wall, already observed during the application of the TMS. A transposition of the focus was performed at this re-operation. There was no transudate in the middle ear and the shunt, which was patent, was left undisturbed.

One patient has some discomfort from autophonia, she hears her own voice as an echo in the treated ear. Another patient has visible movements of the tympanic membrane during respiration as in cases with a patulous tube, but she does not notice it, and she has no discomfort.

Table 2. Results of TMS

4	15	Cortisone Mastoidectomy Middle-ear tube 14 mos. Cortisone	0	March 1969	Transudate

The elevator is then exchanged for a large trochar which has been blunted at the tip. Blunt instruments are used in order to avoid injury to the maxillary artery or its branches. The postero-lateral wall of the maxillary sinus can mostly be penetrated with this blunt trochar. The penetration is otherwise performed after changing the blunt mandrin for a sharp-pointed one with the cannula left in situ. The mandrin is removed and the silicone tube is introduced through the cannula into the maxillary sinus. The length of the tube inside the maxillary sinus is 2-3 cm. The cannula is then removed. The position of the tube is checked by aspiration of air and by instillation of Ringer's solution through the tube, watching for the appearance of the solution from the nasal opening when the head of the patient is turned with the face downwards. The tube is cut obliquely at the end entering the middle ear and the length is adjusted so that the tube reaches about 3 mm below the level of the anterior ligament of the malleus. The tube is fixed with a silk suture to the capsule of the temporo-mandibular joint. The auditory meatus is then packed and the incision sutured.

From the third postoperative day the middle ear is inflated daily through the shunt by Valsalva and Politzer manoeuvres. Myringotomy with aspiration of transudate is usually required after one week or more.

The position of the tube can be checked by X ray.

The application of TMS can be combined with mastoidectomy and with lysis of adhesions in the middle ear. Myringoplasty for small perforations may be performed simultaneously.

RESULTS

Four patients have been operated on according to the method described (Table 1). Their ages ranged from 15 to 47 years. All patients had been treated vigorously for their obstruction of the Eustachian tube before the application of the shunt. All had had an indwelling tube through the drum with temporary recovery but recurrence was seen in all cases when the tube slipped after various periods of time, and one patient had secretion through the tube. Efforts to inflate the middle ear by Valsalva and Politzer manoeuvres and by a Eustachian catheter were unsuccessful. Mastoidectomy had been performed in all patients except one, in whom it was done simultaneously with the application of the tympano-maxillary shunt. One patient, who had an adhesive tympanic membrane, had previously undergone operation with lysis of adhesions, application of silastic sheeting in the middle ear myringoplasty and introduction of a small silicone tube through the Eustachian tube to the nasal opening. This

tube was left in place for one month and used for inflation of the middle ear. All patients had complete obstruction of the Eustachian tube as determined by objective tests of the tubal function also during Valsalva and Politzer manoeuvres, and pressures up to 60 cm H₂O in the nasopharynx did not overcome the resistance.

Transudate was present in the middle ear in all cases at operation. The patient who had had an adhesive tympanic membrane treated with lysis and silastic sheeting during a previous operation, had no adhesions in the middle ear at the application of the shunt, but the tympanic orifice of the Eustachian tube was anatomically completely obstructed.

There were no complications during the operations and healing was excellent (Table 2). The tympanic membranes remained intact. The meatal skin became closely attached to the tube. None of the patients has had acute otitis or sinusitis since the operation. The observation periods since the application of TMS are now from 4 months to 2½ years.

The aeration of the middle ear has been excellent except in one patient, in whom there was a recurrence of transudate after 4 months due to slipping of the tube outside the middle ear cavity but it still lay under the meatal skin. No suture to the temporo-mandibular joint capsule had been used in this patient, who was subjected to re-operation 11 months after the first application of TMS, and the tube, which was still patent, was only pushed a few

Fig. 1 Hearing results in four patients treated with application of tympano-mastoid shunt.

millimetres down in the middle ear and sutured to the joint capsule.

Re-operation was also performed in the patient first operated on, because of fixation of the incus to the lateral attic wall, already observed during the application of the TMS. A transposition of the incus was performed at this re-operation. There was no transudate in the middle ear and the shunt, which was patent, was left undisturbed.

One patient has some discomfort from autophonia: she hears her own voice as an echo in the treated ear. Another patient has visible movements of the tympanic membrane during respiration as in cases with a patulous tube, but she does not notice it, and she has no discomfort.

Table Results of TMS

Case N	Hearing	Aeration of middle ear	Discomforts	Re-operation	Observation during re-operation
1	+	+	(Incompletely restored hearing)	Transposition of incus	No transudate
2	+	+/-/+	Recurrence of transudate due to slipping of TMS	Repositioning of TMS tube	TMS in place
3	+	+	Autophonia	-	Transudate
4	+	+	0	-	Patent TMS tube

The hearing improved in all patients, and has remained within the limits of social hearing since the application of TMS (Fig. 1). An auditory regression occurred after the initial improvement in the patient with the slipped tube (case 2) but it was restored after reoperation.

FUNCTIONAL STUDIES OF THE TMS

The function of the TMS has been tested by simultaneous pressure recordings from the external auditory meatus after application of a cuff and from the nasal opening while the patient was breathing or performing Valsalva manoeuvres. One patient had movements of the tympanic membrane during respiration another had very small movements during intense forced breathing. Drum movements were recorded in the other two patients during Valsalva manoeuvres, but not during forced breathing.

In order to show that the air was passing through the TMS some special tests have been performed (Drettner & Elvall 1969). A movement of the tympanic membrane recorded during the Valsalva manoeuvre was lacking when the same manoeuvre was repeated after tamponade of the maxillary ostium. When air was insufflated into the maxillary sinus through a puncture needle while the tamponade

was still blocking the maxillary ostium, there was again a movement of the tympanic membrane, showing that air was passing only through the TMS and not through the Eustachian tube. Owing to difficulties in obtaining complete blockage of the maxillary ostium, it has only been possible to carry out this test or similar ones in two of the patients. It can therefore not be proved that air may also pass through the Eustachian tube in these cases, although that fact that pre-operative tests showed complete obstruction of the Eustachian tube also after treatment with an indwelling tube, and the observation during the operation in one patient that the Eustachian tube was anatomically completely obstructed, favour the opinion that the ventilation occurs through the TMS. It is conceivable however that a mucosal swelling in the Eustachian tube may be relieved after treatment with TMS.

EUSTACHIAN TUBE FUNCTION IN TYMPANOPLASTY

CLINICAL ASPECTS

L. Ekvall

From the Department of Otolaryngology, University Hospital, Uppsala, Sweden

In order to estimate the significance of pre-operative tests of Eustachian tube function for hearing and healing results, 203 tympanoplasty cases were reviewed. As a routine method Pöfister and Vahvala inflations were used as pre-operative tubal tests. Thirty-nine cases were also tested with the aspiration method. Healed drums were found in 79-97 % of the cases (depending on the type of operation). A serviceable hearing (≥ 30 dB I.S.O.) or an air-bone gap sizes 10 or 15 dB were achieved in 71-96 % of the cases. Cases with negative aspiration tests did not give inferior results as compared with other cases. The investigation suggests that tympanoplasty should not be regarded as contra-indicated on the basis of pre-operative tubal tests. In contrast, postoperative tubal insufficiency, a good hearing, even in the presence of a healed drum, may be attested by way of a tubal by-pass (Arnstrom tube or tympano-mastoid anastomosis).

In the pathogenesis of chronic otitis, hypofunction of the Eustachian tube is undoubtedly of importance. Similarly experimental investigations made by Miller (1965), Flisberg (1966) and Siedentop *et al.* (1968) showed that a very high percentage of cases of chronic otitis have abnormal Eustachian tube function. This abnormality is seen as an inability to equilibrate, by yawning, a negative pressure in the middle ear applied through the external auditory meatus. The above authors reported Eustachian tube hypofunction in 58-76 % of cases of chronic otitis, recorded by the aspiration method. However the relation of this high incidence of hypofunction of the tube to the results of reconstructive middle-ear surgery and especially to the indications for surgery has been unclear. Some authors consider a recorded hypofunction of the tube as a highly unfavourable prognostic sign in tympanoplasty even contra-

indicating reconstructive surgery (Flisberg 1966) Holmquist, 1968). On the other hand, very good healing is reported in large tympanoplasty series without mentioning any tests of tubal function whatsoever (Sheehy & Glasscock, 1967).

In order to find out to what extent this high incidence of Eustachian tube hypofunction in chronic otitis is correlated to healing and hearing, a follow-up study was performed on 203 tympanoplasty cases, operated on between 1963 and 1968. Four cases, operated on during the same period, were not followed up. Three of these died from intercurrent disease and one suffered from severe mental illness.

SURGICAL TECHNIQUE AND POSTOPERATIVE CARE

The surgical technique was almost uniform throughout the series. Tympanic membrane grafting was performed with mesenchymal autograft, vein or temporalis fascia, placed on the medial surface of the perforation. The graft was usually supported by Gelfoam or blood clot in the middle-ear cavity. Even in perforations of moderate size, the whole medial surface of the drum was covered by graft. In cases of large perforations, an extension of fascia (or vein) was inserted between the inner part of the canal skin and the bony meatus to secure an overlap of skin on the graft. Ossiculoplasty when needed, was performed with autografted ossicular remnants, cortical bone or tragal cartilage. In most of the cholesteatoma cases a

closed technique was used. Previously operated radical cavities were obliterated with muscle flaps and/or bone chips. The ear canal was packed with a "rose bud" pack consisting of strips of surgical rayon filled with a synthetic fibre material ("Tactyl"). The pack was left in place for a week and then cortisone antibiotic ear drops were applied locally until complete epithelialization had taken place.

As routine methods for checking the tubal patency pre-operatively Politzer and Valsalva inflations were used. Absence of tubal patency in these tests did not contraindicate surgery since the block could be due to changes in the middle ear accessible at the operation e.g. adhesions or cholesteatoma in the tubal orifice. In 39 randomly selected cases the aspiration test of Flisberg *et al* (1963) was performed as well as Politzer and Valsalva inflations.

Postoperatively Eustachian tube function was followed very carefully. Returning middle-ear ventilation was experienced by the patient as a popping sound when swallowing. If this had not occurred within 8–10 days post-operatively daily Politzer or Valsalva inflations were begun. They were continued until spontaneous middle-ear ventilation was able to maintain an air filled tympanum, a mobile drum and good hearing. In all cases with larger mucous membrane lesions caused by adhesions, tympanosclerosis or cholesteatoma inflation was started on the third or fourth post-operative day without waiting for signs of spontaneous ventilation. During the first 1–2 months after operation all patients were treated with decongestants in the form of vasoconstrictor nasal drops in alternate weeks and with vasoconstrictor antihistamine oral tablets continuously. In addition all patients were instructed to recommence this decongesting therapy prophylactically for 1–2 weeks during every subsequent upper respiratory infection for at least 1–2 years or as long as necessary. With impaired hearing following an upper respiratory infection they were instructed to do Valsalva inflations.

Table 1 *Distribution of the cases on the basis of pre-operative pathology and type of operation. For details see text*

Type of operation	No. of cases
Myringoplasty	81

Primary reconstruction in cholesteatoma	37
Reconstruction in radical cavities	6
Reconstruction in adhesive ears	14
Total	203

MATERIAL

On the basis of the existing pathology and the corresponding type of operation, the 203 cases were divided into five groups (Table 1). The first group myringoplasty comprised ears with drum perforations but with complete ossicular chains, mobile or mobilized at surgery. Cases with drum perforation and stapes fixation as the only ossicular lesion were included in this group. These latter cases were primarily mobilized or secondarily stapedectomized. The second group comprised ears with perforated drums and interruption of the ossicular chain, necessitating myringoplasty and ossiculoplasty. No cases with ossiculoplasty in a pre-operatively closed and ventilated middle ear were included. In this group and in the following a division was made into cases with a complete stapes and cases with the footplate as the only remnant of the stapes. The third group consisted of cholesteatoma cases in which primary reconstruction of the middle ear was performed at the same operation. In all these cases, the ossicular chain was interrupted pre-operatively or had to be removed at operation. Thus no cases were included in which a pre-operatively functioning middle ear could be preserved, i.e. cases of conservative radical operation. A closed technique or obliterative procedure was used in 33 of the 37 cases in this group. The reconstructed radical cavities consisted of cases with absent or severely damaged ossicular chains. Cases with partially

Table 2. The 39 cases in which aspiration test was performed distributed by type of lesion and type of Eustachian tube function according to Miller (1966)

Type of lesion	Miller type				Total
	I	II	III	IV (V)	
Perforation	1	3	2	13	21
Perforation and ossicular lesion	—	2	1	4	7
Cholesteatoma	1	—	1	1	3
Radical cavity	—	2	1	2	7
Adhesive ear	—	—	—	1	1
Total	4	9	5	21	39

preserved middle ears were included in the first two groups. All of the 26 radical cavities were obliterated. The 14 cases of adhesive middle ears had total or subtotal obliteration of the tympanic cavity with loss of the mucous membrane. In most of the cases, the ossicular chain was absent or seriously damaged. Silastic sheeting was used in some of the cases to prevent recurrent adhesions.

The 39 cases with quantitative rubal test (aspiration method) are shown in Table 2. The test was performed according to Flisberg *et al.* (1963) with some modifications. With the patient in the sitting position, a step-wise increasing negative pressure was applied to the middle ear through the external auditory meatus. Pressures of -20 , -50 , -100 , -200

-300 , -400 and -500 mm of water were used. Equilibration followed every level of negative pressure. For each level the patient had to swallow (by drinking water) at least 10 times during 1 minute and pressure changes in the external auditory meatus were recorded. Each test was followed by recorded Politzer and Valsalva insufflations. The results are grouped according to Miller (1965), on the basis of the remaining negative pressure which the patient is unable to equilibrate by further swallowing. No positive pressure was used, so that possible cases of type V according to Miller with complete inability to equilibrate either positive or negative middle-ear pressures, were put down as group IV. The distribution of the 39 cases with aspiration test as regard to pathology and type

of operation was similar to that of the main series. Of the cases, 54 % were unable to equilibrate a negative pressure applied to the middle ear and this figure accords fairly well with the corresponding percentages reported in large series by Miller (51 %) Flisberg (58 %) and recently Siedentop *et al.* (65 %). There seemed to be no definite difference in type of tubal function among the various types of lesion. One of the cholesteatoma cases and four of the radical cavities displayed surprising *by good rubal function*.

RESULTS

All ears were examined by an independent observer as well as by the surgeon. Otomicroscopy and pure-tone audiometry were carried out. Information regarding transient hearing impairment during upper respiratory infections was recorded, in order to estimate the post-operative frequency of a relative tubal insufficiency. Hearing and hearing results are shown in Figs 1-3. Pre and postoperative hearing (in dB LS D) are given as means of the frequencies 500, 1000 and 2000 cps. Filled bars indicate hearing improvement, unfilled hearing impairment. Postoperative bone conduction level is indicated by a horizontal line. In the various groups, the cases are arranged in chronological order from the left and the time of observation is given at the bottom. The shortest time of observation is 6 months. Cases subjected to re-operation are marked with reop

closed technique was used. Previously operated radical cavities were obliterated with muscle flaps and/or bone chips. The ear canal was packed with a "rose bud" pack consisting of strips of surgical rayon filled with a synthetic fibre material ("Tacril"). The pack was left in place for a week and then cortisone antibiotic ear drops were applied locally until complete epithelialization had taken place.

As routine methods for checking the tubal patency pre-operatively, Politzer and Valsalva inflations were used. Absence of tubal patency in these tests did not contra-indicate surgery, since the block could be due to changes in the middle ear accessible at the operation, e.g. adhesions or cholesteatoma in the tubal orifice. In 39 randomly selected cases, the aspiration test of Flisberg *et al* (1963) was performed as well as Politzer and Valsalva inflations.

Postoperatively, Eustachian tube function was followed very carefully. Returning middle-ear ventilation was experienced by the patient as a popping sound when swallowing. If this had not occurred within 8–10 days post-operatively, daily Politzer or Valsalva inflations were begun. They were continued until spontaneous middle-ear ventilation was able to maintain an air-filled tympanum, a mobile drum and good hearing. In all cases with larger mucous membrane lesions, caused by adhesions, tympanosclerosis or cholesteatoma, inflation was started on the third or fourth post-operative day without waiting for signs of spontaneous ventilation. During the first 1–2 months after operation, all patients were treated with decongestants in the form of vasoconstrictor nasal drops in alternate weeks and with vasoconstrictor antihistamine oral tablets continuously. In addition, all patients were instructed to recommence this decongesting therapy prophylactically for 1–2 weeks during every subsequent upper respiratory infection for at least 1–2 years, or as long as necessary. With impaired hearing following an upper respiratory infection they were instructed to do Valsalva inflations.

by a permanently implanted silicon rubber tube, a tympanomastoid shunt (TMS) (Drottner & Ekvall, 1967-1969).

The results of surgery in the five groups are summarized in Table 3 which also demonstrates the frequency of postoperative acute serous otitis, diagnosed from hearing loss during upper respiratory infections. In 10 patients, acute otitis media developed once or repeatedly post-operatively usually with spontaneous perforation of the drum. Nine of them healed with hearing restored, but in one case there is still a small perforation. In the first three groups (myringoplasty myringoplasty and ossiculoplasty primary reconstruction in cholesteatoma) the hearing result was considered satisfactory if the 30 dB level was reached, or if the air-bone gap was closed within 10 dB. In the

RECONSTRUCTION IN RADICAL CAVITIES

Fig. 4. Hearing and healing results in 26 cases of reconstruction in radical cavities. For details, see text.

other two groups (radical cavities and adhesive ears) a postoperative air-bone gap within 15 dB was considered acceptable.

Table 3 *Healing and hearing results in the 203 cases according to type of operation and incidence of acute serous otitis and acute otitis media postoperatively. For details see text*

only way of middle-ear aeration in these patients, but it should prevent locking of the tube and thus permit some spontaneous ventilation.

In spite of very careful decongesting prophylaxis in common colds and acute rhinitis, a high and strikingly constant frequency of acute serous otitis exists in the various groups. In the cases with a negative aspiration test, this frequency is even higher as might be expected. The high incidence of acute serous otitis postoperatively suggests that a relative hypofunction of the Eustachian tube often exists, even after a successful tympanoplasty. This finding is in accordance with those of Sædentop *et al.* (1968) in pre- and postoperative aspiration tests in 25 cases.

The only one of the 21 cases in the group of negative aspiration test that has not reached the 30 dB level has a well-ventilated middle ear and the reason for the remaining air-bone gap is certainly an ossicular problem. The findings in this group suggest that a negative aspiration test does not exclude a good hearing result in the presence of a healed drum. This too corresponds with the observations made by Sædentop *et al.*, viz. that, in most cases it is not possible to predict the surgical result on the basis of pre-operative Eustachian tube function. Even a negative result of patency tests in the form of Valsalva or Politzer inflations, or tubal catheterization, should not contraindicate tympanoplasty as the cause of the block might be adhesive lesions closing the middle-ear orifice of the tube (Zöllner 1963).

In adhesive middle ears there has been some doubt as to whether the Eustachian tube is anatomically open. However clinical observations under the otomicroscope very often disclose an air-filled and closed cavity in the tubal orifice which is conclusive of a functioning Eustachian tube (Wallstein, 1960). This feature could not be demonstrated pre-operatively in eight of the 14 cases of adhesive middle ears in the present series. However in not less than seven of these eight cases which presented as totally obliterated middle ears at operation, was an air-filled cavity lined with normal mu-

cous membrane found in the bony portion of the tube. Neither an aspiration test, nor inflation with any of the available methods would have revealed the ventilating capacity of the tube in these cases. In only one of the 14 adhesive middle ears was an anatomical tubal closure found. The findings in this group suggest that a functioning Eustachian tube often exists, even in adhesive ears, and that the main surgical problem may not be tubal insufficiency but the strong tendency to recurrence of the adhesive lesions *per se*. Middle-ear implants like "Silastic sheeting" could help in the solution of this problem.

The four cases with postoperative chronic serous otitis all reached the 30 dB level after inserting the Armstrong tube or the tympano-maxillary shunt. One of the cases (adhesive ear) had an anatomical tubal closure, and this ear is now well ventilated behind a healed drum via the TMS. Thus, if the tubal function is insufficient postoperatively in spite of active tubal treatment, it is possible to attain good hearing by a tubal by-pass. However the prerequisite is that other parts of the middle ear such as the ossicular chain, have been reconstructed. Finally it is of interest to analyse the hearing results in the 11 cases with postoperative perforation, assuming that all these would be caused by tubal insufficiency. Thus, eight of the 11 cases reached the 30 dB level or closed the air-bone gap within 10 or 15 dB. In no case did the hearing deteriorate.

The present investigation suggests that tympanoplasty should not be regarded as contraindicated on the basis of the result of pre-operative tubal tests. In spite of a high postoperative incidence of relative tubal insufficiency it should be possible to achieve a healed drum and good hearing in a comparatively high percentage of operated cases. In manifest post-operative tubal insufficiency good hearing even in the presence of a healed drum, may be attained by means of a tubal by-pass. Failures should primarily be ascribed to incomplete surgical technique or inadequate postoperative care.

RECONSTRUCTION IN ADHESIVE EARS

Fig. 5 Hearing and healing results in 14 cases of reconstruction in adhesive ears. Hatched bars indicate the hearing after insertion of the Armstrong tube and the TMS. For details, see text

Among the cases with pre-operative aspiration test, special attention was given to those with complete inability to equilibrate the negative pressure in the middle ear by swallowing (Miller type IV (V) cases). The distribution of these 21 patients in respect to type of operation and the postoperative results are given in Fig. 6 and Table 4. The re-operated case was tested between the two operations. One

Table 4. Healing and hearing results and postoperative incidence of acute serous otitis and acute otitis media in 21 cases with negative aspiration test

No. of cases	21
Healed drum	21 (100%)
Perforation	-
Serviceable hearing (≥ 30 dB H.S.O.) or air-bone gap ≤ 10 dB or ≤ 15 dB	0 (95%)
Acute serous otitis in upper respiratory infection	11 (52%)
Acute otitis media	-

case had not reached the 30 dB level, but the middle ear was well ventilated behind a healed drum and the remaining air bone gap was certainly due to a fixation of the stapes, which was mobilized at surgery.

DISCUSSION

The surgical technique used permits a very early postoperative ventilation of the middle ear by Valsalva or Politzer inflations without risk of dislocation of the tympanic membrane graft, which is placed on the medial surface of the drum remnant. Many authors have regarded this early ventilation as extremely important in diminishing the risk of postoperative adhesions and atelectasis of the middle ear (Wullstein, 1960; House, 1960; Zöllner, 1963). An early and regular ventilation during the postoperative period will prevent a long-standing negative pressure in the middle ear. Such negative pressure tends to increase the inevitable postoperative oedema of the mucous membrane caused by the surgical trauma. The tube could then be locked and a vicious circle ensues. The patient himself can very easily continue regular Valsalva inflations until a well-ventilated middle ear and good hearing are established. In exceptional cases, permanent regular inflations have been necessary to preserve a good hearing. These Valsalva or Politzer inflations carried out by the patient himself two or three times a day may not be the

Table 1 *Relation between pre-operative tubal function, postoperative social hearing and recurrent perforation.*

Relation between pre-operative and postoperative tubal function.

Pre-operative tubal function	Total	Social hearing	Recurrent perforation	Not passable in Valsalva's manoeuvre postoperatively
Passable in Valsalva's manoeuvre	44	33 75 %	3	2
Not passable in Valsalva's, but in Politzer's manoeuvre or to catheter	16	9 56 %		5
Stenosis to catheter or Politzer	8	6 75 %	1	3

Total	77	55 71.5 %	10 13 %	12

series and by only 58 % of the patients with poor tubal function.

The follow-up comprised 72 out of the 77 patients. The average follow-up period is 18 months, maximum 4 years. Tubal function was assessed by means of Valsalva's manoeuvre (Table 3). Out of the 65 patients who had had a passable tube in Valsalva's manoeuvre 2-3 months after the operation only 48 had so at follow-up. The results in these patients were still as good as after the operation, social hearing being found in 73 % of the cases. On the other hand, 14 patients did not have a passable tube in Valsalva's manoeuvre at follow-up. These patients hearing had deteriorated somewhat, only 57 % having social hearing as compared with 75 % 2-3 months after the operation.

At follow-up, social hearing was found in 67 % of the total series, i.e. a slightly poorer result as compared with the findings 2-3

months after the operation. This deterioration occurred in the very patients whose tubal function had become worse after the completion of treatment. This indicates the necessity of the patients themselves performing the Valsalva manoeuvre. Out of the 12 patients who had had a non-passable tube in Valsalva's manoeuvre 2-3 months after the tympanoplasty seven again showed patency at follow-up (Table 3). Nevertheless, their hearing had not improved appreciably and the damage caused by the reduced tubal passage after the operation had thus not been materially improved.

The present series demonstrates that tubal function is often somewhat impaired in patients with chronic otitis or the sequelae thereof. Tubal function fluctuates a great deal, and it was not always in the same patients that tubal passage was reduced before the operation, after the operation, and at follow-up. True, the functional results are poorer in patients with

Table 2 *Results 2-3 months after tympanoplasty in 12 patients whose Eustachian tube was not passable in Valsalva's manoeuvre compared with the total series (frequency group 500-2000 cps.).*

			Entire series
Social hearing (0-30 dB.)	6	50 %	71 %
Phone-aux gap (0-15 dB.)	3	25 %	56 %
Hearing improvement more than 10 dB.	6	50 %	8 %
TT) (0-35 dB.)	9	75 %	86 %

Tubal Function and Tympanoplasty

In Glostrup Hospital Copenhagen, tubal function before and after tympanoplasty has been assessed by the Valsalva manoeuvre. Tympanoplasties of types I, II and III, a total of 77 were performed on patients with sequelae of otitis and perforation of the drum but without discharge. The series is unselected, the operations having been performed also upon patients who pre-operatively had considerably impaired tubal function in the hope of improving it. During the operation the tympanic orifice of the tube was inspected, any pathological changes removed, and bougienage was done using a 0.5-1.0 mm rubber bougie which always passed down into the rhinopharynx. One week after the operation the patients started

doing the Valsalva manoeuvre twice daily. In the event of reduced tubal passage, Politzer's manoeuvre was done and air was insufflated through a tubal catheter up to twice weekly for two or three months after the operation.

Prior to the operation the Eustachian tube was passable in Valsalva's manoeuvre in 44 cases (Table 1). 2-3 months after the operation 75 % of these patients had social hearing (30 dB or better to frequencies 500-2000 cps.) In 24 patients, the tube was not passable in Valsalva's manoeuvre, and eight even showed distinct stenosis of the tube in Politzer's manoeuvre or in insufflation of air by tubal catheter. However 15 (63 %) of these patients obtained social hearing, indicating that impaired tubal function does not contra-indicate tympanoplasty. Comparison of tubal function before and after the operation showed that the tubal passage had been improved since after the operation only 12 patients had a non-patent tube in Valsalva's manoeuvre. Out of the 24 patients who had impaired tubal passage in Valsalva's manoeuvre prior to the operation only eight had impaired tubal passage after the operation.

Tubal function during the postoperative period is of great importance for the result. It will be seen that in the 12 patients who had reduced tubal function postoperatively the results are considerably poorer than in the total series, regardless of the criteria by which they are assessed (Table 2). Social hearing was obtained in 71 % of the entire series, but only in 50 % of the patients with poor tubal passage. Closure of a bone-air gap up to 15 dB was obtained in 56 % of the total series, but in only 25 % of the patients with reduced tubal passage. A hearing improvement exceeding 10 dB was obtained by 82 % of the entire series, by only 50 % of the patients with a poor tubal passage. Recurrent perforations occurred in 13 % of the entire series, in 33 % of the patients with a poor tubal function. Social hearing or closure of a bone-air gap of up to 15 dB was obtained by 84 % of the entire

THREE MODELS FOR TEACHING OTONEUROLOGY

N G Henriksson, C F Claussen and L. Tibbling

From the Department of Otolaryngology University Hospital, Lund, Sweden

Two otolith receptors in each vestibular labyrinth record linear accelerations and three ampullar receptors record angular accelerations.

1 *Rotating otolith model*

Purpose: To show that the otolith receptor is inadequate for recording angular movements as the hair of the receptor bends differently at the same angular acceleration if at different distances from the axis of rotation.

2 *Rotating model of a semicircular canal receptor*

Purpose: To show

A. Cupular deflexion is dependent upon angular acceleration and not upon angular velocity

B. This deflexion is independent upon the distance between receptor and axis of rotation.

3 *Model showing transmission of sound-pressure from meatus to inner ear*

Purpose: To show gain in transmission from tympanic membrane to oval window

Fig. 1 Otolith model made of plastic (sensory cells forming the macula), steel (sensory hairs) and silver (otoliths). The model is mounted on a small rotation table. One of the cells can easily be loosened for demonstration of bending of the hair at tilting (45°).

Table 3 *Tubal passage in Valsalva's manoeuvre 2-3 months after tympanoplasty compared with the tubal passage 18 months after the operation*
Relation between tubal function and social hearing

Valsalva's manoeuvre -3 months after the operation				Valsalva's manoeuvre 18 months after the operation					
	Social hearing			Passable	Social hearing	Not passable	Social hearing		
Passable	63	49	75 %	48	35	73 %	14	8	57 %
Not passable	17	6	30 %	7	4	57 %	3	1	33 %
Total	77	55	71 %	55	39	71 %	17	9	53 %

reduced tubal function, but nevertheless the series includes many cases in which the hearing was improved sufficiently to be designated social hearing. The poorest results were seen in cases in which tubal passage had been reduced postoperatively. Therefore, intensive insufflation of air is necessary soon after tympanoplasty.

J. Holmquist Adequate tubal function is a prerequisite for success in tympanoplasty. However, when the surgical procedure includes restoration of tubal function, ears with poor function of the tube may also be subjected to operation. This figure shows 2 year follow up

results after myringoplasty in 94 years. The operative procedure included only covering of the eardrum defect by fascia after de-epithelialization of the drum remnant. Ears with "good" tubal function (according to the aspiration method and equalization into the range of 0-100 mm water) healed in 80 % but only 20 % of the ears with "poor" function healed satisfactorily. This means that the pre-operative tubal function test is able to give prognostic evidence which must not be questioned. However, these results also suggest that the surgical procedure must be focused not only on the eardrum defect, but also on the restoration of the Eustachian-tube function, the middle ear and the mastoid air-cell system.

The tympanic membrane, oval and round windows are made of rubber membranes, ossicular chain of glass rods. The loose connections between ossicles are demonstrated by glass coupling ($1/3$).

PHOTOGRAPHY IN TRANSCONIOSCOPY

II Sørensen

From the Department of Otolaryngology, Municipal Hospital, Copenhagen, Denmark

Transconioscopy has proved valuable in many diseases in the larynx. Transconioscopy should especially be used in the topical diagnosis of laryngeal cancer. In many cases of glottic cancer the caudal extension of the tumour cannot be determined without transconioscopy. Small lesions in the subglottic space that

could not be diagnosed by X-ray tomography and direct laryngoscopy have been revealed by transconioscopy.

The examination is performed in local anaesthesia as described by Mårtensson.

VASCULAR ANATOMY OF THE HUMAN TEMPORAL BONE

C. C. Hansen and A. Mazzoni

From the Department of Anatomy University Hospital Odense Denmark

Temporal bones were removed from the body and afterwards injected with a coloured medium under controlled physiological pressure. Selective injections were performed into the internal auditory or subarcuate artery through the anterior inferior cerebellar artery. The specimens were studied by means of microsurgical dissection methods.

The exhibition showed examples of (A) the vascular anatomy of the cerebello-pontine angle and the internal auditory canal (B) vascular anastomoses within the temporal bone

A 1 Various vascular patterns of arteries extending from the basilar artery to the posterior aspect of the temporal pyramid (into the internal auditory canal and the subarcuate fossa)

2 Different configurations of the anterior inferior cerebellar artery loop plus the internal auditory and subarcuate arteries.

3 Course and division of the single or multiple internal auditory artery inside the internal auditory canal

B 1 Interconnections between the internal auditory and subarcuate arteries.

2 Arterio-venous shunts between the subarcuate artery and superior petrosal sinus

3 Anastomoses between the vertebro-basilar system and branches originating from the carotid arterial system at the level of the ethmoidal bone all around the labyrinth

4 Anastomoses between branches from the

internal auditory and subarcuate arteries and those supplying the middle-ear promontory

Comments

The internal auditory and subarcuate arteries are branches from the same arterial loop, which is either the anterior inferior cerebellar artery itself or its collateral branch. Two or more internal auditory arteries originated from the loop in about one half of the cases. In the remaining specimens only one such artery was found.

Inside the internal auditory canal, the single internal auditory artery usually runs along the anterior or the anterosuperior aspect of the eighth nerve. When present the second internal auditory artery is usually situated along the postero-inferior aspect of the eighth nerve complex.

The subarcuate artery commonly enters the petrous bone at the level of the subarcuate fossa and only rarely through the posterior wall of the internal auditory canal.

A remarkable feature of the peripheral course of both the internal auditory and subarcuate arteries is their distribution to the otic capsule. The branches from these arteries not only communicate freely with each other but in bones injected with contrast medium through vessels both from the carotid artery system branches from the carotid and those from the vertebro-basilar system meet in the same vessels all around the labyrinth. The same is true of the vessels on the tympanic promontory. The tem

poral bone therefore appears as an area in which branches from the intracranial circulation extensively communicate with branches from the extracranial vascular bed. A better understanding of the functional value of such

communications may be of clinical significance.

Finally it should be mentioned that the material injected into the facial nerve sheath from the internal auditory canal side extended as far as beyond the stylomastoid foramen level.

PHONIATRIC DIAGNOSIS

II Fritzell

*From the Division of Phoniatrics Department of Otolaryngology
University Hospital C Ueborg Sweden*

In Scandinavia phoniatrists deal with all kinds of disorders of oral communication. Oral communication is behaviour. From a medical point of view disturbances in a person's speech, voice and language behaviour are symptoms. Thus, phoniatric diagnosis primarily involves analysis and classification of symptoms. Secondly but medically more important, the phoniatrist must find out what causes the symptoms and deviant behaviour and arrive at an aetiological diagnosis. A number of problems pertain to phoniatric diagnosis, such as definitions of normalcy, measuring procedures to determine degrees of abnormality and terminology.

In Scandinavia, phoniatrists deal with all kinds of voice, speech and language disorders. These disorders represent symptoms of a variety of underlying disturbances and diseases which interfere with the normal development of the growing child or with the communicative behaviour of the adult individual, who has well established speech and language patterns. Since the mechanisms of human oral communication are exceedingly complex, the systematic approach to phoniatric diagnosis requires a simplified model to serve as a frame of reference (Fig. 1).

When a speaker wants to communicate a thought to his listener he forms his thought into a code of words and sentences. From his speech motor cortex action potentials representing this code pass through lower levels of the central nervous system and along motor nerves to the vocal tract, where a large number of muscles are activated to transform the signals into sound waves. The sound waves are received by the ear of the listener and the message

again transformed into action potentials. These travel along the auditory nerve and central pathways to the auditory cortex and associated areas, where the message is decoded and perceived. In the control of the speaker's output, his hearing and his tactile and kinesthetic proprioception are the necessary feed back mechanisms.

The phoniatrist is confronted with speakers who do not function normally. In making his diagnosis, he primarily plays the role of the listener. His first task is to analyse the symptoms, i.e. the sound waves and the deviant behaviour of the speaker. Secondly he seeks to find out what has caused the symptoms, to arrive at an aetiological diagnosis. His diagnostic endeavours also include an evaluation of the prognosis, before the therapeutic programme is made up.

Analysis of Symptoms

The analysis of the symptoms is a matter of appraisal and classification of behaviour. In clinical practice, this is almost exclusively carried out by subjective means, i.e. auditorily and visually. The examiner listens to the speech and voice of the patient, and he observes the movements of the articulators, the approximation and vibrations of the vocal folds, the respiratory mechanism, etc. He determines in what respect and to what extent the findings deviate from normal behaviour. For some speech and language functions standardized test procedures are available, which may be

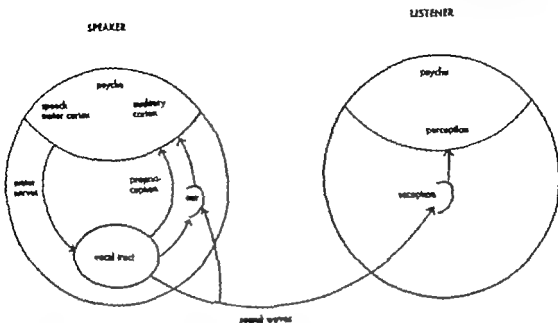

Fig. 1

used to provide measures, and not verbal descriptions only (Johnson *et al.*, 1963).

However as a consequence of the advanced development of medical technology in recent decades, we have very refined procedures at our disposal to record and analyse speech and vocal behaviour *objectively* (van den Berg, 1962). The sound waves emitted by the speaker may be studied in detail by acoustic analysis (Fant, 1960). The flow of air and the air pressure in various parts of the vocal tract may be recorded and measured by aerodynamic procedures (Hardy 1965). The articulatory movements may be subjected to motion-picture analyses, some by regular photography others by X-ray procedures (Kjell, 1965). The activity of the muscles involved in speech production may be studied by means of electromyography (Fromkin & Ladefoged, 1966).

Besides these general approaches to the study of the peripheral speech mechanisms, a large number of special techniques may be used in the detailed analysis of respiration, phonation and articulation. Thus, the vibrations of the vocal folds may be recorded *optically* by stroboscopic photography (van den

Berg, 1960), high-speed photography (Moore & von Leden, 1956) and photoglottography (Sorenson, 1960), *radiologically* by strobolaminagraphy (Holthen, 1965) *electrically* by electroglottography (Fant *et al.*, 1966) and *acoustically* by fundamental frequency analysis (Michel *et al.*, 1966), jitter analysis (Michel *et al.*, 1967), inverse filtering (Lindqvist, 1964) and ultra-sound procedures (Sorenson *et al.*, 1969).

Only to a slight extent have these recording procedures been applied in clinical practice. Their use is still mostly limited to the experimental research laboratories. Moreover as research has so far been concerned mainly with normal individuals, very little objective and quantitative information is available on pathological behaviour.

One of the main features of behaviour that causes considerable problems in phoniatric diagnosis is the normal variation. Speech and voice characteristics vary considerably from individual to individual. These variations are partly due to anatomical differences, but no doubt also to psychological (Moses, 1954) and other factors, such as age. It has been dem-

onstrated that listeners can very accurately tell the age of an unknown speaker simply by listening to his speech and voice from a tape recording (Hollien & Shipp 1967). Speech and voice characteristics also vary considerably within the individual. Thus, it is well known that our voice quality changes with our mood. Another source of variation of particular importance in voice diagnosis is introduced by the examiner when he puts his laryngeal mirror in the throat of the subject, who is holding his mouth wide open and extending his tongue. How does this affect vocal-fold behaviour?

Consequently we are faced with a great deal of variation. This raises the questions: What is normal? What is normal variation? Unfortunately there exists no recognized prototype speaker of Swedish (or any other language) to whom reference can be made, and deviations compared. We have to rely entirely upon subjective standards in the appraisal of our patients. There is an urgent need for more research on normal variation and for standardized test procedures. Thus, no thorough systematic study of Swedish children's language acquisition has yet been made. We do not know definitely at what age our children can be expected to use the correct speech sounds, etc.

Another major problem in phoniatric diagnosis is terminology (Brodnitz, 1967). The way we label the abnormal behaviour of our patients has a great impact on our thinking and handling. But there are very few universally recognized and accepted terms. Thus, it is very difficult—if not impossible—to describe verbally the voice characteristics of a patient in such a way that other readers of his record get a clear concept of his voice. Nor is there any reliable objective way to measure degrees of dysphonia.

Search for Aetiological Factors

Since therapy must primarily be directed towards the aetiological factors, the basic and most important task of the phoniatrist is to find out what has caused the symptoms of his patient.

A great variety of organic and psychological causes may be responsible. Most of the time a combination of factors contributes to the development of a communicative disorder.

A very thorough case history is crucial. Whereas the otolaryngologist may often base his diagnosis and therapy on a fairly brief medical case history and on the findings from the visual examination of his patient, the phoniatrist is also highly dependent on information of the social background and setting of his subject, the development of his speech and language behaviour, his education and present level of communicative sophistication, the professional environment and demands on his voice, etc. It is necessary to devote much time to the case history and to explore all possible causative factors in depth.

In the medical examination of the patient, the psyche, the nervous system, the vocal tract, and the hearing mechanism are evaluated by routine procedures. It must be emphasized that speech and voice disorders may be symptoms of diseases falling within the realm of many other medical specialties. For this reason, the phoniatrist must have a basic training in related areas, thorough enough to make him capable of diagnosing and handling common disorders within the fields of otorhinolaryngology, audiology, neurology, paediatrics, psychiatry, etc., and of making appropriate referrals when necessary.

Making the Diagnosis

On the basis of the analysis of the symptoms the communicative disorder is classified and labelled. The aetiological factors should also be included in the diagnosis. It is advisable to follow the example of the child psychiatrists by keeping the symptom labels and the underlying causes apart. Thus, in the patient records there is room for two diagnoses, the symptom diagnosis and the assumed aetiological factors. Examples.

Phonastenia

Vocal profession + acute laryngitis

Delayed speech development

Congenital hearing impairment

Stuttering

Heredity? + psychic trauma + environment

In this way the behavioural problem is given as a head line, and the aetiological factors are stressed by appearing as subtitles.

Prognostic Evaluation

As part of the diagnostic procedures an attempt is made to assess the prognosis. The examiner determines to what extent present aetiological factors can be influenced or eliminated, and he judges the chances of changing the patient's behaviour by speech and voice therapy. It must be recognized that changing somebody's behaviour is a difficult task. Age and motivation are the main determinants of success. With increasing age, man becomes less flexible tissues gradually lose their elasticity motor patterns stiffen, and mentally we become more rigid. Motivation, however is the most important factor. Without a strong wish to change on the part of the patient and his full co-operation it is very difficult or impossible to influence his behaviour.

CONCLUSIONS

If a comparison is made between otorhinolaryngology and the medical specialties that have grown out of it—audiology and phoniatry the principal differences may be found in the fact that the otolaryngologist—in his capacity as surgeon—is primarily concerned with structure, the audiologist with perception, and the phoniatrist with behaviour. Phoniatric diagnosis means an analysis of deviant behaviour and a search for aetiological factors. The phoniatrist serves as an integrator between medicine and the linguistic and behavioural sciences.

Phoniatric diagnosis is still to a great extent subjective affair where the ear and the eye of the examiner are the most important

tools. In the future, these means should be supplemented by an increased use of instrumental recording procedures and objective standards of evaluation.

PHONIATRIC EXAMINATION TECHNIQUE

N H Buch

*From the Phoniatric Laboratory the Department of Otolaryngology
University Hospital Copenhagen Denmark*

Voice disorders, disarticulations and language disturbances are frontier regions which demand close co-operation between logopaedians, technicians and medical specialists. The experience gained in our recently established Phoniatric Laboratory, its organization, its tasks and the most important equipment required for diagnostic work are mentioned.

The care of speech defectives in Denmark originates from the deaf mute cause. After the preliminary work of pedagogues and physicians, the Government established in April 1898 the Institute for Speech Defectives. The management was then in the hands of the principal of the Royal Institute for Deaf mutes in Copenhagen the Reverend Frederik Heiberg, and Dr Holger Mygind, while C. Goos, LL.D., managing director was the superintendent.

From the earliest annual reports of the Institute it appears that the medical leader was soon dethroned and was later referred to as the "family" doctor connected with the institution. Probably other tasks in the field of the new medical speciality otorhinolaryngology required such enormous efforts from the persons involved that the administration of the care of speech defectives was subsequently left with the pedagogues.

In recent years, increasing activity among psychologists and speech therapists, particularly in connection with the development of the special instruction in council schools and county colleges, has strongly marked the picture on the teaching, educational and administrative levels.

While during the first half of the century the practical work was best done by centralization of the speech institutes, development have now reached a point at which adequate decentralizing is required, but increased activity efficiency, technical improvements and sufficient economy in the work will only be achieved however if diagnostic work and the definition of indications are made more rigorous, and co-operation between the groups involved is further developed.

Moreover the medical contribution to the work for speech defectives in Denmark has so far been too sparse. Instruction of the doctors has been very limited and lack of final positions in the sub-speciality has not inspired young physicians to make this subject their life-work, although it covers—like audiology—so many medical and social aspects that we simply cannot leave it.

It is a well known fact that nearly all speech defects are symptoms of a pathological condition of either organic or psychic origin. Hence, a differentiated medical diagnosis, therapy and instructions form the ideal basis for the efforts of the pedagogue. Testing and objectively reproducible methods of examination as well as frequent check ups of the patients, must be adapted to a system comprising good co-operation between logopedians and phoniatricians with other medical specialists, dentists, psychologists and technicians. This—and also the purchase of clinically and scientifically useful apparatus—can hardly be established in isolated institutions today but will be practicable in

connection with the county-municipal development, which will, *inter alia*, result from the coming administration of the hospital system. The Copenhagen Hearing Centre's move to a hospital area (the Bispebjerg Hospital) is also a natural consequence of similar ideas on the future of radiology.

On this background we have during the past years planned the establishment of a phoniatric laboratory at Rigshospitalet in order to contribute to improved diagnosis, definition of indications and statistics in the field of speech deficiency. The necessity of providing our hospitalized and non-hospitalized patients with sufficient speech therapy when they are most in need of it, has been the practical reason why our Laboratory has been functioning as a unit under the Department of Otolaryngology of the University Hospital, Copenhagen, since the 1st November 1968.

The work is in the hands of a senior registrar from the department and the speech disorders are further handled by two speech therapists recruited from the State Institute for Speech Defectives. The patient material originates from our own department and its out-patient clinic, the other departments of the hospital, practising otologists and other colleagues among the physicians.

During the first 6 months of the existence of the laboratory 345 new patients were examined. On an average, they consulted the laboratory 1.2 times each. Owing to certain practical conditions the therapist coverage was not at a maximum during the said period, but it did comprise 85 days of therapeutical work altogether. During the period, 284 private lessons and 21 classes, consisting, on an average, of five laryngectomized subjects were given. The patients had various organic and psychic complaints, but naturally the co-operation with an ear nose and throat department made speech defects and pronunciation errors predominant. Nevertheless, the language disturbances—including aphasia—constituted one sixth of the treated group. The lessons were carried out without any waiting time, and only nine

patients had not finished their treatment when discharged from hospital. Consequently for geographical reasons, they were referred to local speech therapists all over the country through the Institute for Speech Defectives.

In the diagnostic work, the laboratory has particularly enjoyed the helpful services of the Department of Radiology the Laboratory of Lung Physiology and from special psychiatric, neurological and physiatric examinations. As regards therapy, physiotherapy of various kinds has often been an integrating part. Intensive and frequent speech lessons have been given, and our patients have often had tape recordings of speech exercises for home work. Repeated check-up examinations with tape recordings have in addition to the constant co-operation between physician and speech therapist, contributed to the rationalization.

In the development of the new phoniatric laboratory we have tried to procure apparatus for clinical as well as scientific purposes. The rapid development of electronics will in the future give very high priority to co-operation with engineers, technicians and experimenting phoneticians.

So far we have bought tape recorders, frequency meters, loudness meters, a sonograph, a storage oscilloscope and an electro-acrometer and we have also a Timcke stroboscope at our disposal. We have borrowed a mingograph, and we badly want apparatus for pressure measuring, glottography spectrometry etc.

Partly and fully professional tape recorders are today of such a standard that the choice of make is no longer decisive. We, on our part, use recorders from the Akai-Electric Company. The recordings are made in a sound-absorbing room, which is also an audiometer room. For scientific purposes, dynamic condenser microphones are necessary. The quality of the microphones must be adapted to that of the tape recorder.

In the clinic, it is possible to obtain a rough evaluation of the average speech frequency by using the pitch meter which is incorporated in most stroboscopes. Where the conditions of

frequency are to be reproduced it is necessary to use a frequency meter in addition to the registration apparatus (oscilloscope or mingograph). We use the Danish made "Trans Pitch meter" with two inlets of 5 and 500 ohms with a view to the balance of impedance. Furthermore there are two outputs, as the basic frequency is measurable by simple filtration through five low pass filters, which can be variably inserted depending on the nature of the voice examined. For removal of hum and noise two high pass filters of 60 and 100 cps are included.

The other outlet of the apparatus is intended for the oscilloscope and is specially adjustable for duplex oscillometry which gives special possibilities of sound segmentation. The mingograph only records frequencies up to 800 cps., and that is why in duplex oscillometry the negative half wave is moved upwards by high pass filtration to obtain an intensity curve of the audio-frequency signal in respect of the highest tones. Now the positive and negative curve components are miscible to obtain the best possible segmentation curve. The negative curve unit marks important fricatives and explosives, revealing the high formants hence its vast importance in phoniatric examinations.

The pitch meter is, among other things, applicable in the evaluation of the range of modulation before during and after the speech therapy. Many phonasthenics primarily have a small range and a fairly high-pitched voice. The lessons which often train the deep chest register lower the pitch, and the modulation range is increased. Furthermore, it is possible to ascertain from the curves that the periodical duration of the single fluctuations often vary strongly before the therapy but they are almost uniform thereafter.

The apparatus is devised by the experimental phonetician Børge Frøkjær Jensen, who had already made an intensity meter for the examination of human voices. The instrument is constructed with a special view to phonetic research but may also be used for the exami-

nation of volume e.g. in patients with dysarthria and balbuties.

In recent years, Frøkjær Jensen has worked extensively with glottography at the Phonetic Institute, Copenhagen, and he has, among other things, compared his photo-electric glottograph with the Fabre glottograph. He has prepared an article on the subject for this conference and I shall consequently refrain from detailed mention of the glottograph here.

The sound spectrograph called the Sonograph is made by the Kay Electric Company and used for analysing combined sound waves in the frequency, amplitude and time components. A sound signal of a maximum duration of 2.4 seconds is primarily reproduced on a magnetic disc. Via a filter and a writing device the curves are drawn on calibrated paper the writer working through the range of frequency from the bottom in spiral shaped turns, during which the signal is constantly repeated. The frequency levels activated by the speech produce dark focal points and lines on the teledelta paper. The apparatus offers a possibility of changes in dynamic range (sensitivity), and varying filters can also be applied according to the purpose of the examination. The basic frequency can be calculated just as the individual partial note amplitude can be established by cross section. The apparatus, the principle of which is probably of a somewhat older date, is well suited for several phoniatric purposes. Examinations of pathological noise-filled voices thus show the largest distribution of energy in the lower frequency ranges, while speech therapy moves the energy concentrations upwards in the spectrum. Indistinct articulation appears in broad, ill-defined formant ribbons, while a normal pronunciation manifests itself in narrower and separated linkings. In several neurological speech complaints, deviating intensities and time conditions are further more noticeable in connection with the individual sounds.

For industrial and medical purposes, Brüel & Kjær have during the past year or so made a "parallel analyser" for spectral examinations.

The prototype contains $38\frac{1}{2}$ octave filters with parallel inlet in the range of 22 cps to 45 kcps. The spectrogram appears as filtration columns on a 14-inch cathode oscilloscope screen, on which the abscissa draws the frequency and the ordinate the sound volume in dB. The instrument works with sound-spectrum variations as low as 0.02 second and is thus particularly suitable for vocal examinations. It is able to work with different time constants and comprises four tunings for column adjustment (dynamic range). The apparatus can be fed from tape recorder or microphone, and the picture on the screen frozen by the storage principle. Its outlet signal is transmittable in BCD code to puncher, computer or writer and the sound-volume response of the individual filters are direct readable on a digital band-level indicator. Probably the instrument can be made cheaper for our purposes, which do not require the extremely large frequency range. Furthermore, somewhat narrower filters would be of advantage for phoniatric purposes.

The Electro-acrometer records the quantity of air which, during a defined time unit, passes in and out through the mouth and nose. In addition to these four channels the apparatus has a fifth from a built-in microphone.

The apparatus has been made by Professor Svend Smith, Ph.D. and Assistant Professor Borge Frøker Jensen, M.A. and it is well suited for qualitative and quantitative evaluation of the rhinophonies and of the medical and pedagogic results of their treatment. The principle of this instrument is that the air flow is converted to a pressure on a rubber valve (Momyo), the opening degree of which is registered by means of a ray of light, which is collected by a photodiode through the lumen of the valve. In addition to the four flow trans-

ducers and the microphone, II contains corresponding amplifiers, through which the signal is carried to the mingograph. Besides the flow examinations, the instrument can also be used for judging the vital capacity of the lungs, etc.

Pressure measurements are also of great interest to phoniatricians in their work. Investigations in and over the oesophagus in laryngectomized patients are of importance to the prognosis in relation to oesophageal speech, and evaluation of the sub-glottic and pharyngeal pressure is of importance in other complaints. A new pressure meter made with a transducer particularly suitable for our purposes, is sold under the name of "Manophone".

In phoniatric diagnosis, stroboscopy is a necessary supplement to the indirect laryngoscopy. Several instruments with synchronous microphone control, tone-generator control and phase displacer are now on the market. The method offers a possibility of a differentiated judgement of the pattern of fluctuations, the shape of the vocal cords, the amplitudes, the edge displacement, the glottis inlet and the time relationships of the opening and closing phases, and it contributes in particular to an early diagnosis of firm vocal-cord tumours including cancer. The apparatus is a good help among other things, in the judgement of hormonal voices and the regression of recurrent papillae.

Phoniatrics is a specialty occupying an intermediate position in relation to several others, but most closely related to otorhinolaryngology. It often has to benefit from the services of neighbouring specialties, methods and techniques of examinations, but first and foremost it must seek its own tests, objective measuring methods for the evaluation of the qualities of the voice, speech and language.

ULTRASONIC RECORDING OF THE VIBRATING VOCAL FOLDS

A PRELIMINARY REPORT

C. H. Hertz, K. Lindström and B. Sonesson

*From the Department of Anatomy University of Lund and the Department of
Electrical Measurements Institute of Technology Lund, Sweden*

The ultrasonic echo method has been used to study the vibratory movements of the vocal folds. A special transducer developed for this purpose was used together with commercial ultrasonic equipment designed for heart diagnosis. Well-defined curves of the movement of the vocal folds have been recorded, which confirm the results obtained by other methods. The advantages of the ultrasonic method over other techniques are:

- a. Continuous recording of vibrating vocal folds.
- No interference with the articulatory movements of the tongue and the mandible
- c. No discomfort to the patient, and simplicity of application.

The method can be expected to improve appreciably in definition and resolution if specially designed ultrasonic equipment is used.

In the study of normal speech as well as vocal disorders, the vibratory movements of the vocal folds are of great interest. Several methods have been developed with the object of visualizing the rapid vibratory movements of the vocal folds.

In the present paper a preliminary report will be given of a laryngologic ultrasonographic method for studying the vibratory movements of the vocal folds. The advantage of this method is that a continuous recording can be made of the vibrations without interfering with the articulatory movements and without putting any disturbing instruments into the mouth or pharynx. In fact, the ultrasonic technique is very suitable for studying the larynx because it contains air which gives a maximum reflection of the ultrasound beam.

Method

The ultrasonic echo method has been used for the study of the vibrating vocal folds. The measurements are made with a modern version of the ultrasound reflectoscope developed for non-destructive testing of materials (Firestone, 1945). This technique uses short ultrasound pulses generated by an electrically excited ultrasound transducer and delivered to the material under investigation. This is done by pressing an ultrasonic transducer directly against the surface of the material under investigation. A good acoustical contact is secured by using a thin intermediate layer of oil or ultrasonic jelly between the transducer and the surface of the material.

Each time an acoustic pulse is transmitted, the electron beam of a cathode-ray tube enclosed in the reflectoscope starts moving from the left to the right side of the screen in the x-direction. At the same time, the beam is deflected in the y-direction during the emission of the sound pulse. If the material contains any boundaries which are impinged upon by the sound pulse and which reflect part of the sound back in a direction opposite to its original this reflected ultrasound pulse (echo) will reach the transducer which then acts as a microphone and converts the sound pulse into an electrical pulse. This pulse, after amplification, again deflects the electron beam in the y-direction. Since normally both the sound and the electron beam are moving at constant

speed, the distance to the reflecting boundary can be measured in this way. The method was thoroughly discussed in the paper by Hertz (1967).

Transducer

The vibratory movements of the vocal folds are rather complex, especially in low-tone frequencies. Large surfaces of the vocal folds then contact each other during the closure period of the vibratory cycle. When the opening of the glottis is to occur the complete separation of the vocal folds does not take place instantly; it starts from underneath, the opening progressing upwards, and not until the upper parts have separated does the glottis open (Smith, 1954). To be able to resolve movements from different parts of the vocal folds, a very narrow ultrasonic beam must be used.

In order to decrease the width of the ultrasonic beam at the medial surface of the vocal fold, a transducer was used formed as a focusing bowl with a diameter of 18 mm, a focal length of 24 mm, and a resonance frequency of 2 MHz (Brush Clevite BFB/2C24-5). The material in the transducer PZT-5A, a modified lead zirconate titanate, provides a good compromise between transmitting efficiency and receiving sensitivity for the transducer together with a relatively high mechanical damping.

Apparatus and Recording Technique

The Tekoline 20 ultrasound reflectoscope, manufactured by the Smith Kline Instrument Company Philadelphia, U.S.A., was used in this investigation. The pulse repetition frequency for this apparatus was 1000 Hz, and the pulse length was variable between $0.3-3 \times 10^{-6}$ sec. The ultrasound frequency used was 2 MHz. The apparatus was equipped with some electronic facilities for signal processing, such as time-varying gain (depth compensation) to compensate for ultrasound absorption in tissue and a possibility of delayed sweep, so that

Fig. 1. Block diagram of the recording method in which the ultrasonographic recordings of the vibrating vocal folds are directly displayed on the screen of a cathode-ray tube and photographed with a Polaroid camera.

echoes along the x-axis can be studied enlarged and in detail.

Because of the rapid vibratory movements of the vocal folds, only information of limited value can be obtained by direct inspection of the reflectoscope display. Thus, the movements of the echoes have to be recorded in the same way as is done in the ultrasound-echo technique for heart diagnosis. For the recording of ultrasound cardiograms, three different techniques are in use: the photographic method, the direct recording method, and intensity modulation of cathode ray tube (Hertz, 1967). As the vibratory frequency of the vocal folds is much higher than the frequencies occurring in heart recording, the intensity modulation method has been used in this investigation. Fig. 1 shows that, in this method, the intensity of the electron beam in a cathode-ray tube is modulated by the echo signals from the reflectoscope in such a way that it appears on the screen only when an echo is present (Hertz & Edler, 1956). The sweep voltage from the ultrasound reflectoscope is used to deflect the electron beam along the negative y axis for every ultrasound pulse. Now if the time base of the cathode-ray oscilloscope is running at a suitable deflection speed, say 5 to 10 millisecc./div, the movement curve of the vocal fold can

Fig. 2. Schematic picture of the application of the transducer to the neck of the patient for recording movements of the vibrating vocal folds.

immediately be observed on the screen. To get better amplitude of the movement curves a delayed sweep can be used to enlarge the desired portion of the echo on the CRT screen. For measurement the screen can be photographed with a Polaroid camera.

In the arrangement used a Tektronix 565 double beam oscilloscope has complemented the reflectoscope for the time-motion representation of the movements of the vocal fold.

The main drawback of this arrangement is the relatively low frequency of the transducer which could be higher in order to reduce the physical size of the transducer. This could give a smaller ultrasound beam at the medial surface of the vocal fold. The repetition pulse frequency of 1000 Hz of the reflectoscope used gave only about 10 measurement points in each vibratory cycle, which is rather low. A better repetition frequency for this purpose would be between 6 000 and 10 000 Hz, which could be obtained with modern electronic circuits.

The transducer probe was positioned at the thyroid lamina about 1 cm below and lateral to the thyroid prominence corresponding to the horizontal level of the vocal folds. The probe was placed almost perpendicular to the surface of the neck as shown in Fig. 2. The male subject, who had a normal voice without any organic or functional disturbances in his larynx was instructed to produce a sustained vowel keeping the intensity and frequency of

tone constant. Different vowels were also pronounced to see if any differences in the echo pattern could be observed.

RESULTS

In Fig. 3 a laryngologic ultrasonogram is given showing the structures within the vibrating larynx. The tone frequency of the voice was about 100 Hz and the intensity medium. At the top of the figure the echoes from the thyroid cartilage are seen, and below that, the oscillating echoes from one vocal fold. The vibratory amplitude of the vocal fold is measured to about 1 mm and in the trace the upper peak represents the open position of the vocal fold and the lower part of the trace the closed position. The regular shape of the curve corresponding to the vibratory cycles is found throughout the recordings.

In the echo trace from the vocal fold, the closed interval in each cycle can be seen as a horizontal level more distinct in some cycles and less in others. The most distinct point in the trace is the top, corresponding to the maximally opened position of the vocal fold where as the moments of opening and closing the glottis are less distinctly marked.

The opening phase of the vibratory cycle is measured to about 3 msec, the closing phase to 4 msec and the closed interval to between 2 and 3 msec. This means that the open quotient is 0.7 and the speed quotient 0.8.

For different vowels, the laryngologic ultra-

Fig. 3. Ultrasonic recording of the vibrating vocal fold obtained with the apparatus shown in Fig. 2.

sonogram seemed to have the same appearance, but in the present study no systematic analysis was made on this problem. Further studies are needed for a more conclusive opinion.

DISCUSSION

In the present study the ultrasonic glottogram had the same appearance as that obtained with the photo-glottographic method (Sonnesson, 1960). It means that the ultrasonic method reflects the vibratory movements of the vocal folds, and especially the parts of the vocal folds which have the greatest amplitude, i.e. the vocal ligaments.

Our ultrasonic glottograms also agree well with the calculated displacement curves, which Milne *et al* (1967) obtained by integrating the velocity curves recorded by the Doppler frequency-shift method. The present results seem to indicate that the movement of the vocal folds can be recorded by using the ultrasonic echo method, but that the commercially available apparatus generates too low ultra-

sound frequencies as well as too low pulse rates to give good definition and details of the movement of the vocal folds. Because of this, it is planned to develop ultrasonic equipment specially intended for this purpose.

in the lower and dark in the upper part, a photographic recording (negative) in the scale 1:1 is made and a masterphoto is produced. This will show a dark lower and a transparent upper part and will have the desired signal part as a transitional curve.

The masterphoto is placed on the front glass of the CRT and a photo transducer is placed in the same position to the CRT as the objective of the camera before (Fig. 2). The amplified output of the photo transducer is used as a signal for the oscilloscope Y input. As the electron beam is swept horizontally on the CRT the output from the photo transducer via the vertical (Y) deflection will force the beam to follow the signal curve.

The Y input will then be a copy of the original signal part thus repeated with the same repetition as the beam sweep

Frequency Transformation

Using an external sweep generator (Fig. 3) with variable sweep speed and repetition, it is possible to avoid error signals due to the built in blanking of the electron beam during the fly back time and furthermore to gain a great flexibility in the choice of frequency transformation and repetition.

Reliability

In order to calculate the reliability of the method a sinusoidal signal was used. Sweep time and repetition rate were an even multiple of the period of the base frequency. In the line spectrum theoretically only one of the harmonics corresponding to the base frequency should be measured, but noise limitation will give measurable values for other harmonics. In addition, unlinearity in the oscilloscope and the photo equipment will make a frequency and a phase modulation of the signal.

In this way the dynamic range was determined to be better than 35 dB, and the frequency and the phase modulations corresponding to this dynamic range were better than 15 %

Applications

Examples of the application of this method are given below

Vowels

Fig. 4 shows 8 msec. of a Danish *ae* vowel cut from the exclamation "naeh". The sweep duration is 8 msec. producing a distance between the lines of 125 cps in the line spectrum. In the amplitude-density spectrum measurable amplitude densities in the frequency areas about 200, 500 and 1800 cps are obtained. Only the "ae"-sound spectrum is present in this way and the influence due to the "n" and "h" vocalisation has been suppressed.

EEG

Fig. 5 shows 800 msec. (0.8 sec.) of an EEG recording. The sweep duration is 8 msec., thus producing a frequency transformation of 1:100

A METHOD FOR FREQUENCY ANALYSIS OF SHORT TRANSIENT SOUND SIGNALS

C. Elberling

M Sc. E. Eng.

From the Technical Department and the Department of Otolaryngology County Hospital Gentofte Denmark

A method for frequency analysis of short aperiodic signals is described and its reliability outlined. The method permits specific determination and investigation of the signal parts of interest and furthermore frequency transformation and arbitrary resolution of the frequency spectrum are obtained. Application in the speech and EEG-frequency analysis is demonstrated.

Analysing short aperiodic signals in the low frequency range includes several problems. These are

- 1 Frequency analysis.
- 2 Determination and investigation of the desired signal part.
- 3 Arbitrary frequency transformation of the signal to a convenient frequency range.

Frequency Analysis

Investigating short aperiodic signals, the amplitude-density spectrum of the signal is usually the primary object. Using conventional techniques, this can be measured by repeating the aperiodic signal with a known repetition frequency. The periodic signal thus obtained consisting of a periodically repeated aperiodic signal is used as an input to a conventional audio-frequency analyser. The analyser will then measure an amplitude-line spectrum consisting of a combination of the harmonics to the repetition frequency. Using a low repetition frequency a small distance between the lines in the line spectrum will appear resulting in a good frequency resolution.

The amplitude-density spectrum of the aperiodic

signal will then be the convolution of the measured line spectrum

Determination and Investigation

Fig. 1 shows an output voltage from a microphone. A frequency analysis of the black part is desired. This signal part can be described and determined by its delay

The total signal is displayed on the cathode ray tube (CRT) of an oscilloscope. Using a delayed sweep procedure, the desired signal part (black) can easily be fixed and presented alone on the CRT. After mixing with a high-frequency carrier the CRT picture will be bright

Fig. 1 Determination and investigation of the desired signal part. Production of the masterphoto.

Fig. 2. Perspective view of the set-up.

In the lower and dark in the upper part, a photographic recording (negative) in the scale 1:1 is made and a masterphoto is produced. This will show a dark lower and a transparent upper part and will have the desired signal part as a transitional curve.

The masterphoto is placed on the front glass of the CRT and a photo transducer is placed in the same position to the CRT as the objective of the camera before (Fig. 2). The amplified output of the photo transducer is used as a signal for the oscilloscope Y input. As the electron beam is swept horizontally on the CRT the output from the photo transducer via the vertical (Y) deflection will force the beam to follow the signal curve.

The Y input will then be a copy of the original signal part thus repeated with the same repetition as the beam sweep.

Fig. 3. Interconnection involved: Oscilloscope, photo-transducer pre-amplifier audio-frequency analyser paper recorder and external sweep generator.

Frequency Transformation

Using an external sweep generator (Fig. 3) with variable sweep speed and repetition, it is possible to avoid error signals due to the built in blanking of the electron beam during the fly-back time and furthermore to gain a great flexibility in the choice of frequency transformation and repetition.

Reliability

In order to calculate the reliability of the method a sinusoidal signal was used. Sweep time and repetition rate were an even multiple of the period of the base frequency. In the line spectrum theoretically only one of the harmonics corresponding to the base frequency should be measured, but noise limitation will give measurable values for other harmonics. In addition, nonlinearities in the oscilloscope and the photo equipment will make a frequency and a phase modulation of the signal.

In this way the dynamic range was determined to be better than 35 dB and the frequency and the phase modulations corresponding to this dynamic range were better than 15 %.

Applications

Examples of the application of this method are given below.

Vowels

Fig. 4 shows 8 msec. of a Danish *ae* vowel cut from the exclamation "næh". The sweep duration is 8 msec. producing a distance between the lines of 125 cps in the line spectrum. In the amplitude-density spectrum measurable amplitude densities in the frequency areas about 200, 500 and 1800 cps are obtained. Only the "ae"-sound spectrum is present in this way and the influence due to the "n" and "h" vocalization has been suppressed.

EEG

ELECTRICAL STIMULATION OF THE HUMAN RECURRENT LARYNGEAL NERVE DURING THYROID OPERATION

K. Flinberg and T. Lindholm

From the Departments of Otolaryngology and the Medical Department B (Renal Clinic), University Hospital Lund, Sweden

A method for identification of the human recurrent laryngeal nerve during thyroid operation is described. It is based on electrical stimulation of the nerve and recording of the muscle action potentials in the vocal muscle with needle electrode inserted through the cricothyroid membrane. The recurrent laryngeal nerve could be easily identified in all of the 13 patients (13 nerves) investigated. The motor nerve conduction velocity in the recurrent laryngeal nerve was also studied and found to be 48.6 ± 3.3 m/sec.

In his anatomical studies of the recurrent laryngeal nerve Lanz (1955) noted great variations in its course. This means that the recurrent laryngeal nerve is exposed to the risk of being damaged by incisions on the neck, especially for thyroid operations. The risk is, in particular great in re-operations, because of the excessive scars around the trachea, and also in operations for large tumours, which can displace the nerve. In operations for malignant tumours of the thyroid it is often necessary to remove one or both of the thyroid lobes completely or partially. It is important that the recurrent laryngeal nerve be spared in radical operation, provided that this does not interfere with the complete removal of the tumour. In radical operations the nerve must therefore be identified and protected against injury. Hawe & Lothman (1960) presented a series of 1011 patients, in whom the recurrent laryngeal nerve was isolated in operations for various thyroid disorders. Vocal-cord paralysis developed in 48 cases and became permanent in three. According to an analysis by Mcnaman (1951), the risk of causing damage to the recurrent laryngeal nerve in primary thyroid surgery

ranged from 0.3 % to 13.2 % in different series. In re-operation the risk increased to between 10.0 % and 15.4 %. The corresponding rates of complications are virtually unchanged in later reports (Wade, 1955; Riddell, 1956; Blomstedt & Rydmark, 1960; Haw & Lothman, 1960). According to Labey (1944) and Hawe & Lothman (1960) the isolation of the nerve, in itself involves only a slight risk of injury. In thyroid operations the risk of injury to the recurrent laryngeal nerve will thus be greater if the nerve is not identified and isolated.

We present here a simple and clinically usable method for the identification of the recurrent laryngeal nerve in operations. The technique applied also enabled us to study the conduction velocity in the nerve.

Previous Methods

Shedd & Burget (1966) and Shedd & Durham (1966) described an objective method of electrical identification of the recurrent laryngeal nerve. An air-inflated balloon was applied between the vocal cords and connected to a manometer. On electrical stimulation of the nerve a rise in pressure in the balloon was noted, indicating muscular activity in the intrinsic laryngeal muscles. Prytz *et al.* (1965), using concentric needle electrodes, studied the muscular activity in the intrinsic laryngeal muscles through a laryngoscope or during total laryngectomy. In 29 cases, the stimulation was performed through needle electrodes inserted percutaneously near the nerve, either at its cran-

and a distance between the lines of 125 cps in the line spectrum. The EEG frequencies are transposed from the frequency range 1-20 cps into the range 100-2000 cps, permitting the use of a conventional audio-analyzer. Plotting the line spectrum the frequency axis is re-transformed into the original range.

Most energy is obtained in the range 6-10 cps corresponding to an α -rhythm, and a smaller amount at 13-15 cps corresponding to a β -rhythm.

ELECTRICAL STIMULATION OF THE HUMAN RECURRENT LARYNGEAL NERVE DURING THYROID OPERATION

K. Filberg and T. Lindholm

From the Department of Otolaryngology and the Medical Department B (Renal Clinic), University Hospital, Lund, Sweden

A method for identification of the human recurrent laryngeal nerve during thyroid operation is described. It is based on electrical stimulation of the nerve and recording of the myoelectric action potentials in the vocal muscle with a needle electrode inserted through the cricothyroid membrane. The recurrent laryngeal nerve could be easily identified in all of the 13 patients (15 nerves) investigated. The motor nerve conduction velocity in the recurrent laryngeal nerve was also studied and found to be 48.6 ± 3.5 m/sec.

In his anatomical studies of the recurrent laryngeal nerve Laeiz (1955) noted great variations in its course. This means that the recurrent laryngeal nerve is exposed to the risk of being damaged by incisions on the neck, especially for thyroid operations. The risk is, in particular great in re-operations, because of the excessive scars around the trachea, and also in operations for large tumours, which can displace the nerve. In operations for malignant tumours of the thyroid it is often necessary to remove one or both of the thyroid lobes completely or partially. It is important that the recurrent laryngeal nerve be spared in radical operation, provided that this does not interfere with the complete removal of the tumour. In radical operations the nerve must therefore be identified and protected against injury. Hawe & Loftham (1960) presented a series of 1011 patients in whom the recurrent laryngeal nerve was isolated in operations for various thyroid disorders. Vocal-cord paralysis developed in 33 cases and became permanent in three. According to an analysis by McCrann (1951), the risk of causing damage to the recurrent laryngeal nerve in primary thyroid surgery

ranged from 0.3 % to 13.2 % in different series, in re-operation the risk increased to between 10.0 % and 15.4 %. The corresponding rates of complications are virtually unchanged in later reports (Wade, 1955; Riddell, 1956; Blomstedt & Rydmark, 1960; Hawe & Loftham, 1960). According to Lahey (1944) and Hawe & Loftham (1960) the isolation of the nerve, in itself involves only a slight risk of injury. In thyroid operations the risk of injury to the recurrent laryngeal nerve will thus be greater if the nerve is not identified and isolated.

We present here a simple and clinically usable method for the identification of the recurrent laryngeal nerve in operations. The technique applied also enabled us to study the conduction velocity in the nerve.

Previous Methods

Shedd & Burget (1966) and Shedd & Durham (1966) described an objective method of electrical identification of the recurrent laryngeal nerve. An air-inflated balloon was applied between the vocal cords and connected to a manometer. On electrical stimulation of the nerve a rise in pressure in the balloon was noted, indicating muscular activity in the intrinsic laryngeal muscles. Peytz *et al.* (1965) using concentric needle electrodes, studied the muscular activity in the intrinsic laryngeal muscles through a laryngoscope or during total laryngectomy. In 29 cases, the stimulation was performed through needle electrodes inserted percutaneously near the nerve, either at its cra-

nially ascending branch or at the vagus nerve. After measurements on corpses, the length of the nerve in the patient was calculated, and the authors were then able also to determine the conduction velocity in the nerve in eight cases. The nerve conduction velocity was 60–70 m/sec.

Electromyographic studies of the intrinsic laryngeal muscles have previously been made, for instance, by Faaborg Andersen (1957) who inserted the recording electrode into the investigated muscles through the pharynx. Hiroto *et al.* (1962) described a transcutaneous method for electromyographic studies of all the intrinsic laryngeal muscles. Their method was used and improved by Hirano & Ohala (1967).

Methods

We used a bipolar needle electrode, DISA type 13 K 14 (six nerves) or a bipolar electrode DISA type 13 K 33 (nine nerves) for stimulation of the recurrent laryngeal nerve. The electrodes were applied direct on the nerve,

cranially and caudally in the operating field (Fig. 1). Stimuli were rectangular supramaximal current pulses, 0.2 msec. in duration passed from a DISA Multistim or from a DISA stimulator unit, type 14 E 11. The distance between the stimulation sites on the nerve was kept constant by placing a measure, 30 mm in length close to the nerve. The stimulation response in the intrinsic laryngeal muscles was recorded through concentric needle electrodes DISA type 13 K 51. The needle electrode was inserted through the cricothyroid membrane positioned so that its tip was in the vocal muscle (Fig. 1). In most cases the position of the needle electrode could be altered so that an initially negative phase of the muscle action potential was obtained, indicating that it was situated in the end plate region. The muscle action potentials were amplified and recorded in a three-channel electromyograph, DISA type 13 A 69 or in a one-channel electromyograph DISA type 14 C 10 (Fig. 2). The sweep speed was 0.25 msec/mm and 0.1 msec/mm, respectively. The conduction velocity in the nerve could be determined, as the distance between the two stimulation sites and the difference between the conduction times from the two sites were

Fig. 2. Action potentials in the vocal muscle under stimulation of the recurrent laryngeal nerve at two different sites 30 mm apart.

known. The temperature at the nerve was recorded in 10 cases with an Electric Universal Thermometer type TE 3 (Erlab Copenhagen). As applicator was used an electrode with a thermo-junction (type K 8).

Material

Thirteen patients (15 nerves) were investigated during operation for thyroid tumours. The average age of the patients, 12 women and one man, was 47.6 (26-68) years. Eight of them (eight nerves) were operated on for adenoma of the thyroid and 5 (seven nerves) for cancer of the thyroid. In four of the latter the investigation was made at re-operation. The type of anaesthesia was the same in all the cases and consisted of neuroleptic anaesthesia induced with Leptanal® plus Dridol® nitrous oxide and oxygen after premedication with atropine.

RESULTS

The recurrent laryngeal nerve was easily identified in all the cases.

Motor-nerve conduction velocity in 15 nerves averaged 48.6 ± 3.5 m/sec (S.D. 13.7 m/sec). Stimulation of the nerve at the cranial site evoked a muscle action potential with a latency averaging 1.8 ± 0.07 msec. (S.D. 0.6 msec). The temperature at the nerve was 34.2 ± 0.3 °C.

A thorough examination of the mobility of the vocal cords was made in all the cases before and after operation. In none of the cases was any form of paralysis or trauma of the vocal cord observed.

DISCUSSION

Labry (1944), Capps (1958), Elner *et al.* (1968) and others have all emphasized the importance of identifying the recurrent laryngeal nerve in any type of thyroid operation. When the nerve is readily identified, but the procedure can cause the surgeon difficulties.

The technique described here permits exact identification of the recurrent laryngeal nerve at dissection, and nerve injury can thus be avoided.

In two cases it was noted that the cricothyroid muscle contracted in response to stimulation of the recurrent laryngeal nerve. The contraction was strictly unilateral. This finding would probably mean that the cricothyroid muscle can be innervated also from the recurrent laryngeal nerve. However, this abnormal innervation of the cricothyroid muscle was seen and described more than a century ago by Bach (1834) after anatomical preparations:

Rarissime tandem nervus recurrens ramum internum ad muscolum cricothyroideum mittit Bach noticed this type of innervation in one of eight investigated corpses. A reflex stimulation response in the cricothyroid muscle over the superior laryngeal nerve through an afferent impulse in the recurrent laryngeal nerve is another possibility as, according to Mündnach (1956) there are sensory nerve endings in laryngeal muscles of man. An argument against this hypothesis is that contraction of the cricothyroid muscle on stimulation of the recurrent laryngeal nerve occurred in only two out of our 13 patients.

The motor-nerve conduction velocities observed were lower than those reported by Peytz *et al.* (1965). But they used a somewhat different technique: they stimulated the nerve percutaneously and extrapolated the conduction distance from measurements on corpses. On the other hand, it may be noted that the segment over which we measured the conduction velocity was only 30 mm, which introduces a factor of uncertainty in the measurements.

We stimulated the recurrent laryngeal nerve during operations in which the nerve was dissected free and consequently exposed to some degree of chilling. The temperature of the nerve was found to be about 3 °C lower than normal body temperature. If the influence of temperature on conduction velocity in the recurrent laryngeal nerve were the same as in the ulnar nerve (2.4 m/sec °C) (Henriksen,

Fig. 1 Sites of the recording needle electrode (I) and the nerve stimulation electrode (II).

nially ascending branch or at the vagus nerve. After measurements on corpses, the length of the nerve in the patient was calculated and the authors were then able also to determine the conduction velocity in the nerve in eight cases. The nerve conduction velocity was 60–70 m/sec.

Electromyographic studies of the intrinsic laryngeal muscles have previously been made, for instance by Fanborg Andersen (1957) who inserted the recording electrode into the investigated muscles through the pharynx. Hiroto *et al* (1962) described a transcutaneous method for electromyographic studies of all the intrinsic laryngeal muscles. Their method was used and improved by Hirano & Ohala (1967).

Methods

We used a bipolar needle electrode, DISA type 13 K 14 (six nerves) or a bipolar electrode, DISA type 13 K 33 (nine nerves) for stimulation of the recurrent laryngeal nerve. The electrodes were applied direct on the nerve,

cranially and caudally in the operating field (Fig. 1). Stimuli were rectangular supramaximal current pulses, 0.2 msec. in duration passed from a DISA Multistim or from a DISA stimulator unit, type 14 E 11. The distance between the stimulation sites on the nerve was kept constant by placing a measure, 30 mm in length close to the nerve. The stimulation response in the intrinsic laryngeal muscles was recorded through concentric needle electrodes DISA type 13 K 51. The needle electrode was inserted through the cricothyroid membrane positioned so that its tip was in the vocal muscle (Fig. 1). In most cases, the position of the needle electrode could be altered, so that an initially negative phase of the muscle action potential was obtained, indicating that it was situated in the end-plate region. The muscle action potentials were amplified and recorded in a three-channel electromyograph, DISA type 14 A 69 or in a one-channel electromyograph DISA type 14 C 10 (Fig. 2). The sweep speed was 0.25 msec/mm and 0.1 msec/mm, respectively. The conduction velocity in the nerve could be determined as the distance between the two stimulation sites and the difference between the conduction times from the two sites were

Fig. 2 Action potentials in the vocal muscle under stimulation of the recurrent laryngeal nerve at two different sites 30 mm apart.

muscle relaxant is used for the intubation in order to avoid curarization of the patient during the stimulation.

We have employed this procedure in operations for thyroid adenoma, in which injury to the recurrent nerve might be caused, and, in particular for thyroid cancer in which total thyroidectomy is performed, or total hemi-thyroidectomy on one side and partial on the other

U. Strala. The anatomical preparation of the recurrent nerve may not be necessary to avoid impaired nerve function in ordinary goitre cases. It is indicated in carcinoma—and in the difficult cases. It is important to investigate the laryngeal function pre- and postoperatively—otherwise a number of lesions will remain undiagnosed. Phoniatric treatment of the voice improves the prognosis considerably

1956) the nerve conduction velocity transposed to normal body temperature would be on an average, 56 m/sec.

As some malignant diseases can produce neuropathy (Croft & Wilkinson 1965) we compared the nerve conduction velocities in our five cases of thyroid cancer with those in the eight cases of non-malignant thyroid adenoma no difference was noted.

DISCUSSION

H Rasmussen In the Department of Otolaryngology of the Finsen Institute Copenhagen, we have, for nearly 2 years, used electrical stimulation of one or both recurrent nerves in certain thyroid operations, with simultaneous recording of action potentials from one or both vocal cords. A DISA Multistim and electromyograph are used in the procedure.

After intubation of the patient, a concentric or bipolar electrode is placed in one or both vocal cords by means of a Negus laryngoscope inserted in front of the tube. The electrode is placed a little anteriorly to the middle of the vocal cord where the end plate region is. During the operation we stimulate the recurrent nerve. Its course is followed by moving the electrode until potentials are obtained at the lowest intensity which means that the stimulus is delivered on or around the recurrent nerve. This procedure has proved useful in avoiding lesions of the nerve. A short acting

Fig. 1 Potential from the right vocal cord on stimulation of the right recurrent nerve by 11 μ V amplification 100 μ V sweep speed 1 msec/mm stimulus duration 0.1 sec.

in greater detail. A concert singer comes to a doctor's office. She complains that she is completely hoarse. To the doctor the voice sounds clear and beautiful, though there does appear some cracking at the pitch of e^3 (659 cps.) The vocal cords seem normal. The next patient, a labourer, has come to have wax removed from his ears. The patient insists that he is otherwise perfectly healthy. In the doctor's opinion, his voice sounds hoarse and in the examination, cancer of the larynx is diagnosed. It is a well-known and unfortunate fact that, for instance, cases of laryngeal cancer generally come under treatment only when the disease has reached an advanced stage. Hoarseness (as an acoustic phenomenon) is not regarded so much as a symptom of a disease but as a personal characteristic, like one's handwriting or red hair (cf. the nickname given to a person with a hoarse voice: 'Croaky'). In ancient times, the voice was regarded as something "körperlich" or bodily. Besides, as a symbol of sexuality hoarseness has had its own prophets.

The way of using one's voice is the same as a way of life. There are ways of life which reveal themselves as hoarseness. Because of this, many voice disorders going under the name of chronic laryngitis are hopelessly difficult to cure. Patients willingly give up their tonsils, for example, but not their harmful habits. Local treatment of such symptoms of secondary laryngitis (erythema, oedema, increased secretion of mucus, pachydermia¹ and even nodules and polyps by painting the throat and inhaling is approximately the same as trying to dry up a waterfall by drawing off the water below the fall instead of applying these measures above the fall. In cases of voice disorder this means that treatment should be turned away from local therapy to the realm of voice use and personal problems.

Personal problems show themselves in the voice in many ways. In aphonia psychogenica,

the patient suddenly becomes hoarse, or starts whispering, for an emotional reason. Nevertheless, coughing is possible, which is a sign that there is no paralysis of the organ. This has been held to be a symptom of a desire to kill, to die, or to be unborn (Moses, 1954). Reality is experienced as too oppressive, and so there is an escape into regression. One manifestation of this is dysphonia plicae ventricularis (Arnold & Pinto, 1960) in which a phylogenetically older function gains the ascendancy in the functioning of the larynx. The result is that the ventricular folds are compressed in phonation, so that the vocal cords cannot function. One form is dysphonia spastica, which Kliml (1963) divided into six subgroups. Features of these situations are relatively small local changes in the vocal cords, spastic, tight, snatchy breathing and voice. "Communal vocalization" (Hallen, 1959) for instance, shouting at a football match, can at times be easily managed. On the other hand, in situations which are in one way or another significant to this person, communication by means of the voice is very difficult. These cases "very often sail under the false flag of chronic laryngitis".

Even if simple forms are the exception and complex forms the rule, from the practical point of view one should bear in mind that laryngitis caused by infection is worst in the morning and that caused by voice strain is worst in the evening. A psychogenic voice disorder changes suddenly and apparently inconsistently. A hormone-based disorder appears to remain more stable.

A function of a definite kind proceeds most economically if its structure is optimal. An exception to this "functional optimum" means that the voice disorder is becoming latent. A change in the function is influenced by psychological factors, habits, "voice culture" a change in the structure caused by infections, and also by different hormone disturbances, growth of the larynx, etc. If the function does not follow the growth of the larynx, the consequence is the disorder of the maturational voice. In boys, the voice breaks

¹ The surgical removal of these is sometimes sufficient for improvement of the voice but nevertheless it is only treatment of symptoms.

PHONIATRIC VIEWPOINTS ON HOARSENESS

A. Sonninen

From the Phoniatric Department, Central Hospital, Jyväskylä, Finland

Many things can be indicated by hoarseness, in the examination of which at least four different levels, not to be confused with each other, must be taken into account. (a) the psychological, (b) the anatomical, (c) the patho-physiological, (d) the patho-anatomical. A description of the above levels will be followed by a discussion of the mechanism of voice strain. A new theory is formulated, according to which vocal nodules develop chiefly as a result of excessive loading on the tensor ligaments in incorrect open voice phonation.

Hoarseness is a general term for voice symptoms which may be caused by any disease or disorder of the larynx. Although hoarseness is relatively common, statistics concerning it are scanty and they are very defective and even controversial. Whereas according to Nadoleczny (1926) as many as 41.6% of school-children had chronic hoarseness, in an extensive investigation in the American Speech and Hearing Association's Committee Report on the Midcentury White House Conference on Children and Youth (1952) the figure for the 5-21 age-range was only 0.2%.

There are several reasons for the defectiveness of the statistics. In the phylogenetic sense phonation is a new, secondary and thus unstable function. In the pressures of social intercourse and the demands of civilisation the larynx has, to a considerable degree, been forced to change from its original primary functions of swallowing and breathing. In adapting itself to phonation the larynx in some respects has to work "against nature". In phonation one has to learn to free oneself from some of those disturbing reflexes which are connected

with the primary functions, of which the most important is surely the mechanism of swallowing (Ruth, 1952). The most economical, the most effective and furthermore the least tiring use of the vocal cords is, for this reason, by no means inborn, but it must be learnt by everyone, frequently with difficulty and it demands practice. Seeing that the prerequisites for learning the ability to use one's voice—musicality, anatomical conditions, illnesses, etc.—vary and the prototypes which influence the use of the voice right from the earliest childhood as well as one's culture etc. regulate the learning process, one should not be surprised by the variations in the human voice and in its use nor by the fact that some people do not learn to use their voice "correctly" at all. Another reason for the defectiveness of the statistics is to be found in the vague and multi-layered nature of the concept of hoarseness.

In this paper I want to throw some light on this question by examining four different levels of hoarseness, namely the psychological, the acoustical, the physiological and the anatomical.

1. *On the psychological level* the way in which the patient himself experiences everything is decisive. In contrast to people in the worlds of bel canto and the art of public speaking, the man in the street does not usually regard hoarseness as anything peculiar. Let the following two cases illustrate this question.

in greater detail. A concert singer comes to a doctor's office. She complains that she is completely hoarse. To the doctor the voice sounds clear and beautiful, though there does appear some cracking at the pitch of c^3 (659 cps.) The vocal cords seem normal. The next patient, a labourer has come to have wax removed from his ears. The patient insists that he is otherwise perfectly healthy. In the doctor's opinion, his voice sounds hoarse and in the examination, cancer of the larynx is diagnosed. It is a well-known and unfortunate fact that, for instance cases of laryngeal cancer generally come under treatment only when the disease has reached an advanced stage. Hoarseness (as an acoustic phenomenon) is not regarded so much as a symptom of a disease but as a personal characteristic, like one's handwriting or red hair (cf. the nickname given to a person with a hoarse voice "Croaky"). In ancient times, the voice was regarded as something *körperlich* or bodily. Besides, as a symbol of sexuality hoarseness has had its own prophets.

The way of using one's voice is the same as a way of life. There are ways of life which reveal themselves as hoarseness. Because of this, many voice disorders going under the name of chronic laryngitis are hopelessly difficult to cure. Patients willingly give up their tonsils, for example but not their harmful habits. Local treatment of such symptoms of secondary laryngitis (erythema, oedema, increased secretion of mucus, pachydermia and even nodules and polyps) by fanning the throat and inhaling is approximately the same as trying to dry up a waterfall by drawing off the water below the fall instead of applying these measures above the fall. In cases of voice disorder this means that treatment should be turned away from local therapy to the realm of voice use and personal problems.

Personal problems show themselves in the voice in many ways. In aphonia psychogenica,

the patient suddenly becomes hoarse, or starts whispering, for an emotional reason. Nevertheless, coughing is possible, which is a sign that there is no paralysis of the organ. This has been held to be a symptom of a desire to kill, to die, or to be unborn (Moses, 1954). Reality is experienced as too oppressive, and so there is an escape into regression. One manifestation of this is dysphonia plicae ventriculares (Arnold & Pinto 1960) in which a phylogenetically older function gains the ascendancy in the functioning of the larynx. The result is that the ventricular folds are compressed in phonation, so that the vocal cords cannot function. One form is dysphonia spastica, which Klink (1963) divided into six subgroups. Features of these situations are relatively small local changes in the vocal cords, spastic, tight, scratchy breathing and voice. "Communal vocalisation" (Kallen, 1959) (for instance shouting at a football match, can at times be easily managed. In the doctor's opinion, his voice sounds hoarse and in the examination, cancer of the larynx is diagnosed. It is a well-known and unfortunate fact that, for instance, cases of laryngeal cancer generally come under treatment only when the disease has reached an advanced stage. Hoarseness (as an acoustic phenomenon) is not regarded so much as a symptom of a disease but as a personal characteristic, like one's handwriting or red hair (cf. the nickname given to a person with a hoarse voice: 'Crowly'). In ancient times, the voice was regarded as something *körperlich* or bodily. Besides, as a symbol of sexuality hoarseness has had its own prophets.

The way of using one's voice is the same as a way of life. There are ways of life which reveal themselves as hoarseness. Because of this, many voice disorders going under the name of chronic laryngitis are hopelessly difficult to cure. Patients willingly give up their tonsils, for example, but not their harmful habits. Local treatment of such symptoms of secondary laryngitis (erythema, oedema, increased secretion of mucous, psoriasis¹ and even nodules and polyps by painting the throat and inhaling is approximately the same as trying to dry up a waterfall by drawing off the water below the fall instead of applying these measures above the fall. In cases of voice disorder this means that treatment should be turned away from local therapy to the realm of voice use and personal problems.

Personal problems show themselves in the voice in many ways. In aphonia psychogenica,

the patient suddenly becomes hoarse, or starts whispering, for an emotional reason. Nevertheless, coughing is possible, which is a sign that there is no paralysis of the organ. This has been held to be a symptom of a desire to kill, to die, or to be unborn (Moses, 1954). Reality is experienced as too oppressive, and so there is an escape into regression. One manifestation of this is dysphonia plicae ventricularis (Arnold & Pinto, 1960) in which a phylogenetically older function gains the ascendancy in the functioning of the larynx. The result is that the ventricular folds are compressed in phonation, so that the vocal cords cannot function. One form is dysphonia spastica, which Kiml (1963) divided into six subgroups. Features of these situations are relatively small local changes in the vocal cords, spastic, tight, snatchy breathing and voice. "Construal vocalisation" (Kallen, 1959) for instance, shouting at a football match, can at times be easily managed. On the other hand, in situations which are in one way or another significant to this person, communication by means of the voice is very difficult. These cases "very often sail under the false flag of chronic laryngitis".

Even if simple forms are the exception and complex forms the rule, from the practical point of view one should bear in mind that laryngitis caused by infection is worst in the morning and that caused by voice strain is worst in the evening. A psychogenic voice disorder changes suddenly and apparently inconsistently. A hormone-based disorder appears to remain more stable.

A function of a definite kind proceeds "most economically" if its structure is optimal. An exception to this "functional optimum" means that the voice disorder is becoming latent. A change in the function is influenced by psychological factors, habits, "voice-culture" a change in the structure caused by infections, and also by different hormone disturbances, growth of the larynx, etc. If the function does not follow the growth of the larynx, the consequence is the disorder of the mutational voice. In boys, the voice breaks

¹ The surgical removal of these is sometimes sufficient for improvement of the voice, but nevertheless it is only treatment of symptoms.

PHONIATRIC VIEWPOINTS ON HOARSENESS

A. Sonninen

From the Phoniatric Department Central Hospital Jyväskylä Finland

Many things can be indicated by hoarseness, in the examination of which at least four different levels, not to be confused with each other must be taken into account. (a) the psychological (b) the acoustical, (c) the patho-physiological (d) the patho-anatomical. A description of the above levels will be followed by a discussion of the mechanism of voice strain. A new theory is formulated, according to which vocal nodules develop chiefly as a result of excessive loading on the tensor ligaments in incorrect open voice phonation.

Hoarseness is a general term for voice symptoms which may be caused by any disease or disorder of the larynx. Although hoarseness is relatively common, statistics concerning it are scanty and they are very defective and even controversial. Whereas according to Nađoleczny (1926) as many as 41.6% of school children had chronic hoarseness, in an extensive investigation in the American Speech and Hearing Association's Committee Report on the Midcentury White House Conference on Children and Youth (1952) the figure for the 5-21 age range was only 0.2%.

There are several reasons for the defectiveness of the statistics. In the phylogenetic sense, phonation is a new, secondary and thus unstable, function. In the pressures of social intercourse and the demands of civilisation the larynx has, to a considerable degree, been forced to change from its original primary functions of swallowing and breathing. In adapting itself to phonation, the larynx in some respects has to work "against nature". In phonation, one has to learn to free oneself from some of those disturbing reflexes which are connected

with the primary functions, of which the most important is surely the mechanism of swallowing (Ruth 1952). The most economical, the most effective and furthermore the least tiring use of the vocal cords is, for this reason, by no means inborn, but it must be learnt by everyone frequently with difficulty and it demands practice. Seeing that the prerequisites for learning, the ability to use one's voice, musicality, anatomical conditions, illnesses, etc. vary and the prototypes which influence the use of the voice right from the earliest childhood as well as one's culture etc. regulate the learning process, one should not be surprised by the variations in the human voice and in its use, nor by the fact that some people do not learn to use their voice "correctly" at all. Another reason for the defectiveness of the statistics is to be found in the vague and multi-layered nature of the concept of hoarseness.

In this paper I want to throw some light on this question by examining four different levels of hoarseness, namely the psychological, the acoustical, the physiological and the anatomical.

I. On the psychological level the way in which the patient himself experiences every thing is decisive. In contrast to people in the worlds of bel canto and the art of public speaking, the man in the street does not usually regard hoarseness as anything peculiar. Let the following two cases illustrate this question.

radiates to the neck, to the ears, to the root of the nose, etc.). They are more noticeable in phonation than during silence but neuralgic and other troubles are clearly noticeable.

2. On the *acoustical level*, hoarseness must be examined from the point of view of auditory experience. The parallelism between the physico-acoustical changes and the psycho-physiological occurrences of the medium is an important area of research in the problem of hoarseness. Here one has to move between two extremes, on the one hand, research into the changes of pressure in the medium is not by itself enough, because changes of pressure need not necessarily be sound. The pressure impulses have to be such that they are capable of creating a psychic sound experience via the sensory organs. On the other hand, an experience without the equivalent vibrations of the medium is by no means sound, but an auditory illusion, a hallucination. When examining an auditory experience, it is therefore always necessary to take into account both the physical stimulant and the hearer and also the fact that the learning process as well as the psychological factor influence the creation of an auditory experience. Thus, auditory habits and the process of learning to hear are factors that must not be overlooked, even when discussing the problem of hoarseness. For example, it is a well-known fact that, far too often, patients suffering from cancer of the throat unfortunately come under treatment too late, partly because they have not learnt to listen for and correctly interpret the first symptom of cancer—namely hoarseness. Traditional misconceptions exist about the physico-acoustical phenomenon. More often than not one reads in papers and textbooks that frequency intensity and time are the physical components or parameters of speech sounds, as if the Fourier components were physical realities indeed! As a matter of fact, "the only physical reality of speech sound is the time function depicting the barometric pressure as a function of time. Physical realities are

the zero crossings" and "the whole pattern of nervous activity in the acoustic nerve is governed by the ability of the nerve endings to indicate zero crossings (Mol, 1962). Consequently it is extremely important to observe that the voice with its various features is in the end always a subjective experience. Objective methods can never replace or bypass subjective voice analysis. An accurate objective description of all the various vocal nuances seems to be an impossible task, at least at the moment. Just imagine attempting to describe objectively the following adjectives, for instance, all of which are used in describing the singing voice: (visual) bright, clear limpid, pale, cloudy muddy dark, (caloric sense) salty warm, cold, icy (kinesthetic sense) strained, forced, breathy firm, tight, husbed, lifting, relaxed, scooping, sliding, wobbly biting, strident, supported, tense vibrant, resonant (anatomical) back, front, head-mouth-throat chest-nasal, naked, strangled, (instrumental) flute-like, piping; (material) metallic, brassy wooden, woolly gravelly airy (spatial) broad, narrow flat, rounded (aesthetic) beautiful, ugly pleasing, unpleasant; (taste) sweet, sugary dulcet, mellow and also the adjectives rich and lustrant. Vocal training and professional singing are almost entirely based on such subjective concepts. Subjective analysis is also important in the investigation of hoarseness. Ishiki and his colleagues (1969) observed that the ear is so far probably the most important instrument for measuring hoarseness. Using Osgood's semantic differential method, he finally selected four factors from among the 260 adjectives which describe the voice, for which he used the names Degree (D), Breathiness (B), Rough (R), and Aesthetic (A) which may be recognised by ear in a statistically significant way when using a 4-point scale. He recommends this method for use in clinical work. The R-factor is due to the cycle-to-cycle fluctuation of the fundamental frequency and appears on a statistically significant level, for instance, in cases of polyps of the vocal cords. In cases of cancer of the vocal cords the

in a more noticeable way than in girls, as well as more slowly and later. Cracking of the voice appears relatively seldom. If a disturbance occurs in the boy's father identification, a "permanent falsetto" may be a "tönender Beweis" (vocal evidence) of this (Moses, 1954). The same happens in a milder form in incomplete or delayed breaking of the voice. It is a question of a purely functional disorder. The patient plays the cello as though it was still the violin. Very often this kind of 16-18 year-old youth is taken to the doctor by his mother. By pressing lightly on the thyroid cartilage in the direction of the dorsal during phonation a strong and deep man's voice is usually found immediately. It is a professional error to forbid such a patient to use his voice, to send him to hospital for weeks and to say that he has "catarrh" or a "weak throat". These cases are often wrongly treated with antibiotics, as inflamed and swollen vocal cords are an integral part of this illness. In girls, the disorder of a breaking voice is evident in too low a speaking voice. This is also incorrectly diagnosed as "catarrh" or "hysteria". In school, they sing in chorus second voice against the great number of singers who sing first voice. During the time when the voice breaks, school singing might in other respects be harmful to the voice. These purely functional voice disorders are relatively common. They are to be distinguished from the less common voice disorders which are caused by hormones.

A person who lives by his voice or for his voice more than other people experiences even a small change in the voice caused by external agents as a vague, frightening threat. This is the case, for example, with endogenous and iatrogenic virilizing symptoms. Bauer (1968) in histological investigations, observed that the amount of muscular tissue increases in such cases, and the result is an increase in the vibratory mass. The doctor's assurances that everything is in order do not bring comfort. The result is a secondary neurotization. Unfortunately the use of anabolic steroids appears to be increasing. The consequences are reflected

in an increase in cases of voice disorders ("laryngitis chronica") in surgery and in the literature (Arndt, 1960; Timonen *et al.* 1962; Bauer 1963; Damsté 1964). The worst thing is that voice symptoms come stealthily and much sooner than other virilizing symptoms. The deviation from the functional optimum has to be compensated for and the voice disorder remains latent until some temporary agent (a "cold" infection, voice strain, etc.) makes the symptoms noticeable. The causal connection remains unnoticed and the treatment is symptomatic. Unfortunately this kind of organic change in the voice frequently persists. Here, too, prevention is more fruitful than treatment. In the opinion of Berendes (1968), it is advisable to make the patient aware of the possibility of virilizing side effects before treatment begins.

It is often likely that the doctor adopts the same attitude towards hoarseness as the patient. The patient complains of hoarseness to the phoniatrist or laryngologist, but of a completely different trouble to the doctor who gives anabolic steroids. It is always the patient who poses the questions: it is he who asks for help. It is the doctor's duty to try to help him. And of course, nothing bad can be said about this. It is only important that this should be borne in mind when dealing with the problem of hoarseness.

Patients experience hoarseness in various individual ways. The reason for going to see a doctor is not always primarily an acoustic change in the voice but rather what the patient feels in his throat during phonation. Certain emotional disturbances and an uneconomical use of the voice become projected into the laryngeal area and they are experienced as "hoarseness" ("The voice becomes tired" when they mean that the larynx becomes tired.) In a carefully taken medical history it often becomes apparent that hoarseness is the same as in various paracathesiae of the throat region (itching irritation in the throat, the need to swallow a sensation of dryness, roughness, burning, a lump in the throat, pain that

According to Nessel (1960), the most typical feature of a hoarse voice is noise above 5000 cps. Yamagihara (1964) taking into account, on the one hand, the progressive disappearance of the harmonics and, on the other the corresponding increase of the noise component, especially in the second and third formant ranges of vowels, discerned on sonograms four degrees of hoarseness.

The primary factor in auditory experience, and thus also in hoarseness, has been held to be the behaviour of the pressure impulse of the medium. If the frequency of the impulse, which determines the pitch of the fundamental frequency changes aperiodically from impulse to impulse (cycle-to-cycle) hoarseness is experienced, called in English jitter 'harshness' or 'roughness'. Wendahl (1963) observed that even such a small variation as ± 1 cps caused hoarseness to be experienced at a pitch of 100 cps. The hoarseness was greater if the variation was increased to ± 10 cps. It was interesting that a ± 10 cps variation caused a smaller sensation of hoarseness at a pitch of 200 cps than the same variation (± 10 cps) at a pitch of 100 cps. This means that the same aperiodic vibration of the vocal cords sounds hoarser to a man's voice than in a woman's. Coleman & Wendahl (1967) observed that the duration of the voice signal also affects hoarseness. One semitone jitter conditions of 0.32 sec., 0.64 sec., and 0.80 sec. durations should correspond in roughness to three-seconds stimuli with approximate durational values of 0.75, 0.40, and 0.50 sec., respectively. A sound heard for a shorter time thus sounds clearer than a sound heard for a longer time, although the latter may in fact be more aperiodic than the former. Thus, we have the paradox: a rough voice is clearer than a clearer voice.

The sensation of hoarseness may be caused by cycle-to-cycle amplitude variations of the impulse without jitter. Wendahl (1966) uses the name 'shimmer' for this kind of roughness. It was noticed then that larger variations lead to greater hoarseness being experienced. It is practically impossible to differentiate between

hoarseness caused by shimmer and hoarseness caused by jitter. A third factor causing hoarseness, partly containing both the foregoing factors (jitter and shimmer) are the variations in the form of the impulse, which were visible in Sørensen's glottograph (1962). In hyperkinesia, the impulse changes were more abrupt than normal, in phonasthenia the closed phase was sometimes absent, and the third type showed cycle-to-cycle variations in the relative duration (opening quotient) of the closed phase.

Of the foregoing forms of hoarseness 'vocal fry' (Michal & Hollica, 1968) is the one which is clearly distinguishable by ear. It may appear both in pathological cases and in healthy persons below the normal chest register (average vocal pitch 36.4 cps). Here the fundamental frequency is periodic and regular. The characteristic is an almost complete (over 30 dB) damping occurring between each impulse (Wendahl, 1963, 1966; Coleman, 1963). The noise peculiar to hoarseness may originate either in the glottis or elsewhere. Aerodynamic and neuromuscular phenomena occurring in the glottis are, therefore, central to the problem of hoarseness.

Cooper (1964) too, observed that in addition to random modulation, regular sinusoidal modulation can result in a sensation of hoarseness. "When the pulse train is completely regular the voice is, of course, completely monotone. If the frequency of the pulse train is varied up and down a little bit once or twice a second, this serves to break the monotone completely and produces something that is fairly close to satisfactory speech except that it tends to be sing-songy and, occasionally the pitch goes up at the end of a sentence when it should have gone down. If the pulse train is modulated at a somewhat higher rate, on the order of 3 to 5 cycles per second, the voice is like that of an old man talking with a voice that creaks and breaks. This corresponds to what Dunker & Schlossbauer (1964) observed in a high-speed film in which the vocal cords of an old, hoarse sounding man vibrated completely symmetrically and periodically. Further

Infiltrating growth has fixed the loose mucous membrane to the underlying structure. This results in the suction caused by the Bernoulli effect becoming difficult, the voice becoming breathy and the B-factor becoming more noticeable. The practical result of this is, for instance, that if hoarseness has continued for more than 3 weeks in a 40-year-old patient it might be a case of cancer of the vocal cords especially if there is breathiness (factor B) in the voice.

The voice is made up of a fundamental frequency and harmonics, and in fulfilling aesthetic requirements, the voice has to be governed by a certain conformity and a lack of noise element between them. According to Winckel (1952, 1953) there are in a good singing voice a certain number of harmonics whose peaks must be under 1200 cps. Another smaller peak is required in the region of 3000 cps and between these two regions (1200 cps and 3000 cps) there is a trough. The harmonics are regulated apart from the resonance cavities, in a remarkable way by the frequency duration and the form of the primary impulse itself. In a low pitched voice there are more harmonics than in a high pitched one, and they increase with the duration of the impulse. Changing from an open way of singing to a covered way the harmonics decrease (Winckel 1952, van den Berg & Vennard 1959, Gemelli *et al.* 1954, Large, 1968, 1969, Somninen 1962, 1969) which signifies a prolongation of the opening phase of the vocal cords and an increase in the consumption of air (Luchsinger 1951). Van den Berg & Vennard (1959) observed that the "ring" of the singing voice signifies a peak in the region of 2800–3200 cps, the "twang" one in the region of 3000–3500 cps, whereas in a "honk" the harmonics have disappeared above 1000 cps.

Objective electro-acoustical investigations are irreplaceable for making a subjective analysis more accurate and complete.

According to Berger (1937) aperiodicity of the fundamental frequency and the appearance of unharmonic (unharmonische) harmonics

were peculiarities of pharyngeal-voice and recurrent paralysis. In addition the occasional splitting of the fundamental pitch into two voices or jumps between certain intervals (2:3 or 3:4) known as diplophonia, appeared. Curry (1953) observed that in the voice of a post encephalitis patient the aperiodic vibrations were 37.5 % of the phonation, whereas he estimated that in a normal speaker they are only 2.7 %. It was found in addition, that there was exceptional intonation in the pitch of the speaking voice and the fundamental frequency was too low. According to Lafon & Cornut (1959) three kinds of bitonal sound exist: harmonious diplophonia (les sons bitonaux harmoniques), true diplophonia (les sons bitonaux vrais) and successive diplophonia (les sons bitonaux successifs). In harmonious diplophonia, the lower fundamental frequency is the subharmonic harmonic of the higher fundamental frequency. This occurs in a badly controlled voice. In true diplophonia, two fundamental frequencies with their own harmonics are heard simultaneously. This occurs, for instance, in hypotony of the vocal cords, as the mass and tension of the vocal cords are asymmetrical. In successive diplophonia, the fundamental frequency varies by a certain interval. This occurs, for instance, in mutation disorders. Schönhörl (1962) came across cases of voice disorder in which both the fundamental frequency and the harmonics were missing, and there was only noise in their place. This was the case, for example, in functional aphonia, tumours, and different substitute voices (Ersatzstimme). In addition to the fundamental frequency only one or two harmonics and their replacement by noise may occur in cases of acute laryngitis, the formation of cicatrices, papilloma, keratosis, and hyperkeratosis. A stronger fundamental frequency and distortion of the harmonics and their replacement by noise may occur in vocal nodules, polyps, papillomata, and in cases of recurrent papilloma and functional hyperkinesis. In addition, he observed bitonality in the same way as Lafon did.

where, as in Rubin & Hirtz (1960) high-speed film, three mechanisms may appear "open chink" where the rima does not close, "closed chink" where the rima closes, and "damping" where part of the rima is closed all the time and part is open. The middle register is more or less the transitional region between one mechanism and another.

Regularity of glottal air-pressure impulses and of vocal cord vibrations is a prerequisite for a clear voice. The duration of the vibration period determines the pitch of the fundamental frequency and of the harmonics and also to a large extent the number of the harmonics. The relation of the duration of the impulses to the duration of the period is called the "opening quotient" (OQ). It is "fraction of cycle during which the glottis is open/duration of entire cycle". It determines in a fundamental way the form of the voice pattern. The amplitude of the impulse determines the volume of the voice, and it also affects the number of the harmonics. In addition, the quality of the voice is affected by: (1) the speed at which the impulse reaches its maximum point. This corresponds approximately to the speed at which the glottis opens (opening phase). (2) The speed at which the impulse regains a state of inaction. This corresponds to the closing speed of the glottis (closing phase). (3) The time during which the glottis remains closed (closed phase). The term "speed quotient" (SQ) is used for the relation between the opening and the closing phases. OQ increases with the pitch of the voice; SQ increases with the volume of the voice.

The earliest direct observations of the pathological vibrations of the vocal cords were made with the aid of a stroboscope. Thus, Maljutin observed in 1931 asymmetrical vibrations in voice disorders. A diseased vocal cord seemed to vibrate less, at times also more extensively than a healthy one. Maljutin conjectured that the reason for this was the failure of a kind of proprioceptive reflex system ("Automatismus der Stimmblindernebstregulierung"). Maljutin did not see the vocal cords

vibrating above 1000 cps. When the vibrations were missing below this level, the quality of the voice was not the same as when the vocal cords did vibrate. The dispute which dates from this time as to whether the non-vibration of the vocal cords which has occasionally been noticed is either real or only apparent seems to have been settled in favour of the latter alternative with the help of recent high-speed films (4000-8000 frames per second).

Von Leden *et al* (1960) observed that in all benign disorders of the vocal cords (including paralysis) the vocal cords always vibrate, and that the diseased vocal cord affects the manner in which the healthy one vibrates. Tumours and oedema cause a quicker than usual damping of the vibration, whereas a slack, paralysed vocal cord vibrates more extensively than a tense, healthy one. Increased subglottic pressure adds to this difference. Differences generally appeared, exceeding the medial line in phase and amplitude but not in frequency in the vibrations between the healthy and the diseased parts. Frequent and rapid changes in the regularity of the vibratory pattern were the commonest symptom.

It has been possible to observe that the hoarser the voice, the more irregular are the vibrations, OQ and SQ of the vocal cords, cycle-to-cycle. Thus, Moore & Thompson noticed in 1965 that the random fundamental frequency shift of a hoarse person fluctuates, on an average, 7.04 cps and of a person hoarser than him, 8.69 cps.

On the basis of their research, Dunker & Schlottbauer (1964) arrived at "a scale of voice disorders in the presence of vocal cords macroscopically unaltered. At the smallest injury only the course of the single vibration was disturbed (for example, a change of the glottis closure time), while the periodicity was preserved. Possibly this was a reflex influence on the muscle from the receptors of the altered mucous membrane. The next degree was demonstrated with the slight constitutional phonasthenia. Also in this case was the periodicity of vibration preserved, but checking all vibra-

more in Coopers's experiment, "at a little higher rate of modulation about 7 cycles per second, the effect is more nearly that of a vibration, and not unpleasant. At higher rates of say 15-30 cycles per second, the speech is extremely rough and unpleasant; this effect gradually fades out but is still quite noticeable even when the rate of modulating the pulse train approaches the voice pitch itself."

3. On the physiological level the glottis is the main object of investigation. From the point of view of lung physiology the key point must be held to be the pulmonary alveolus where blood circulation and ventilation both meet. The larynx is only one part of the ventilating system. The "key point" of voice physiology on the other hand is the rima glottidis in which the subglottic pressure, the speed of the flow of air and the vibrating properties of the vocal cords (mass, tension) must be in the right relationship to each other (pneumophonic co-ordination) from the important initial moment (attack) of phonation. The bulbar breathing centre appears to have the possibility of influencing this position in two ways: firstly through the breathing muscles directly, and secondly through innervation to the vocal cords themselves (Kirikae *et al.* 1962). Thus, the aerodynamic and neuromuscular processes are under the control of the bulbar centres. The complicated aerodynamic neuromuscular processes in the glottis form a basis for the quality of the sound that is developed. Ishiki & von Leden (1964) noticed that the consumption of air in a hoarse voice need not always be greater than normal. The reason for this was the hyperfunctioning of the vocal cords and greater glottal resistance than usual, which is influenced in a decisive way by the outer tension of the vocal cords. The volume of the voice is increased by glottal resistance and/or increasing subglottic pressure. "Changes in the muscle activity pattern directly affect the aerodynamic patterns and the final acoustic properties - the voice signal".

From the physical point of view "the prin-

cipal source of energy in voice sounds comes from the self-excited oscillations of the vocal folds, caused by the flow of air between them. The primary feedback mechanism that makes possible and sustains oscillation is the Bernoulli effect". In addition, "quite important are secondary feedback paths that start with stimuli from the ear and from kinesthetic receptors in the vocal muscles. The mechanical interaction between the air flow and fold vibration is rather small, and acoustical effects become important only when strong resonances exist. In physical terms, the vocal folds may be idealized as a string of fairly constant mass, but of variable tension and length that is fastened to its surrounding structures by tissue that adds variable mass, stiffness, and damping" - "If we consider the ligaments and muscles in the vocal folds to be similar in passive action to that of a rubber band, then it is easy to demonstrate that when such a system is stretched, the length is roughly proportional to the stretching force or tension. Thus, the frequency of vibration is changed but slightly when such a vibrator is stretched. However if we deal with a much less extensible system, such as an ordinary piece of string, then the frequency of vibration depends markedly on the tension. The actual behaviour of the vocal folds appears to be a mixture of rubber-band like and string-like in their action at higher frequencies, whereas at lower frequencies they are more rubber band-like" (Salmon, 1964).

How then, does the vibration of the vocal cords in a hoarse voice differ from the normal?

The opinions of research workers as to how the vocal cords vibrate within the normal registers and in different pathological situations have lately supported each other in rather many respects. In the chest register the vocal cords are relatively slack, vibrate throughout their breadth, length and depth, and the lower margin of the vocal cords is in the opposite stage of vibration to that of the upper margin. The rima becomes closed. In a head voice the vocal cords are tense, taut and only small vibrations can be noticed in their medial margins.

comes before them, however. Some unfortunate cases of carelessness still occur in this respect. Taking a sample is still the only way in unclear cases. On the other hand, taking samples unnecessarily and carelessly must be avoided as unevenness as well as a defect of the margin of the vocal cords may lead to chronic hoarseness. Cauterization should also be avoided. If a sample is not taken immediately the case must be kept under careful observation. The cytological test and an examination with a stroboscope may be helpful in determining the moment when a sample should be taken. I myself have come across three cases of hoarseness in which it was not possible to notice any thing out of the ordinary with an ordinary examining mirror but in which stroboscopic examination revealed that one vocal cord vibrated noticeably less, the sample taken on the basis of this showed that it was a case of cancer. I will not on this occasion go into the various causes of hoarseness and the patho-anatomical changes connected with them, as they do not belong to the present subject. I believe that more causes of hoarseness can be found than the 50 mentioned by Jackson in 1939. Generally speaking, hoarseness is a symptom which directs the therapeutic attention of the doctor to the basic disease itself, which may be a tumour, paralysis, etc. Hoarseness alone is for him of no great importance. If the vocal cords are inflamed or swollen, it is normally regarded as a symptom of an infection, and the patient is prescribed an antibiotic cure, even a lengthy one, regardless of the fact that an antibiotic cure seldom affects the bacterial flora of the pharynx and larynx. Neither the histological, nor the clinical pattern of laryngitis is in reality purely infective. Text book descriptions correspond more or less precisely with each other although the heading might be for instance chronic laryngitis (Thompson & Negro, 1948), "laryngopathia funktionelle" (Tarnaud, 1950), or Phonasthenie (Flatau-Imhof 1913 Blegvad, 1955). Apart from laryngitis caused by a specific infection (bois, TB), it is normally a ques-

tion of a tangle of multi-dimensional symptoms and aetiological factors, whatever name it may be given.

In this connection I would like to discuss one cause of voice disorders which is normally brushed aside in a couple of words, namely voice strain.

What is the mechanism of voice strain? It is most commonly held that the vocal cords striking together (*coup de glotte*) at the beginning of a sound and the friction between them is an incorrect use of the voice are the most important mechanisms. The significance of the vibration junctions (*Schwingungsknotenpunkten*) is hardly regarded any longer as being important. Tarnaud (1935) thought that the cause of vocal-cord nodules was general hypotony of the larynx musculature. The consequence of this is that the junctions of the anterior and middle thirds of the cords, where the vibration amplitude is the greatest, are in a position to strike against each other (*"les deux cordes vocales vont se presser l'une contre l'autre et se choquer à chaque vibration avec le maximum d'intensité"*) Palodetti & Stirpe (1964), basing their view on histological investigations, wanted, in addition, to put forward the theory that the nodule would be of traumatic origin from the wrenching of vocal muscular fibrils at the level of their insertion in the inferior thyroid-arytenoid ligament. Köhn's thoughts (1959) also turn in the direction of the subepithelium. Taking histological investigations as the basis, he presents two mechanisms for injury of the vocal cords. (1) Primary injury of the mucous membrane caused by external irritants, such as tobacco smoke, dust, etc. They lead to papilloma, pschydermia, leukoplakia, and Bowen's disease under the effect of certain additional factors. (2) Primary injury of the subepithelial tissue. This is, above all, due to the incorrect use of the voice and voice strain. The result is a vocal nodule or polyp. It is remarkable that the epithelium in vocal-cord nodules, for instance, is normal, and the histological changes are seen in the subepithelial tissue.

tions of a tone revealed jump-like shifts of the opening and closure time possible as an expression of a positioning weakness of the vocal muscles. The cases coming next in severity also revealed definite phase differences with preserved periodicity. This may be due mainly to muscular weakness. Finally in strong hoarseness there were distinct disturbances of the periodicity with large amplitude differences and continuously changing glottis widths.— In these cases as further reaching disturbances of the reflex function circles must be present, with the surprising fact that instillation of a vasoconstricting compound in menthol oil temporarily resulted in a certain symmetry of the vocal-cord vibrations with normal periodicity."

What, then, causes the irregularity of the vibrations of the vocal cords?

In paralysis, tumours and other organic voice disorders the mechanism appears to be easier to understand. In functional voice disorders, on the other hand, organic prerequisites for regular vibrations should exist.

Dunker & Schlosshauer (1964) observed in experiments with animals that after changing the tension of the cricothyroid muscle momentary irregularities appeared in the vibrations of the vocal cords. Rubin & Hirt (1960) photographed with high speed films the break up of regular vibratory movement into complete chaos when an untrained singer changed from chest register to falsetto (break). In such vibratory chaos, the proprioceptive reflex system probably fails. Changes in the tonus of the muscular fibres occur which reverberate as changes in the vibratory properties of the vocal cords from one moment to the next. Voice training showed itself capable of curing this disorder. Brewer *et al.* (1960) indicated in EMG investigations a more persistent co-ordination and tonus disorder of the laryngeal muscles in cases of voice disorder. These were corrected as a result of successful voice therapy. It is interesting to remark that co-ordinatory disorders and hoarseness of the voice can be observed in physiological states in different pho-

nation mechanisms of very small children (Sedláčková, 1967; Wasz Höckert *et al.* 1968; Lind 1965).

The observations explained above clearly seem to indicate that vibrations of the vocal cords are regulated by an inner reflex system whose temporary or more permanent failure causes irregularities in the vibrations of the vocal cords. According to Wyke (1969) there are three inner reflexes: (1) the subglottic mucosal mechanoreceptor reflex which reacts quickly and sensitively to changes in subglottic pressure and thereby regulates the tonus of the intrinsic adductor muscles; (2) the laryngeal articular mechanoreceptor reflexes, of which especially the crico-arytenoid and the cricothyroid innervated from the capsules of the joints, are the most important. These react very sensitively and quickly to the movements of the cartilages controlling the nucleus ambiguus through the tonus of the intrinsic laryngeal muscles attached to the laryngeal cartilages; and (3) the laryngeal myotatic reflex system which is a slow reflex controlling the tonus of the muscles.

According to Wyke, in principle, a functional voice disorder can thus be caused by two types of co-ordinatory disorders, of which one is cortical voluntary and connected with learning and the other is subcortical, involuntary and dependent on the neuromuscular maturity of the reflex system. Even if according to present-day ideas, Huxson's neurochronaxia theory presented in 1950 has been unquestionably proved faulty, it seems that neurological factors in a different form play a considerable part in the onset and treatment of voice disorders. In future investigations of voice disorders one ought to delve even more thoroughly into such neuro-phoniatric problems.

4. On the patho-anatomical level the histological and cytological examination of the vocal cords occupies a central position in the problem of hoarseness. But the examination of the larynx with the help of a mirror which every doctor must be able to perform,

the ligaments prevent further stretching of the vocal cords (Sonninen, 1954, 1956, 1962, 1969; van den Berg, 1960; Arnold, 1961; Rubin & Hirt, 1960; Damsté, 1968). From the moment when the voice rises, another mechanism has to be brought into action (*cf.* head-voice mechanism). We know from experiments that a high voice is more tiring than a low voice, and that at a high pitch the voice easily becomes a shout. If we wish to conserve the voice, it is advisable to speak with a low voice, when the vocal cords are less taut, and it is easier to speak softly. In raising the pitch in singing, one has to learn to "cover" the voice above a certain pitch. The "open way of singing, which comes naturally tires the voice. When the voice rises in the open way of singing, the larynx rises and tenses. Subglottic pressure is increased, and the result is that the higher the singing pitch the more the voice shouts. Then, at a certain point, the voice breaks and becomes completely different, thin and "falsetto-like".

In the covered manner of singing, the larynx does not rise as the voice rises, but remains near the inactive level. I have been able to confirm in my x-ray measurements that in phonation the vocal cords are shorter and thinner, the sinus Morgagni is larger and the larynx is nearer the resting level than when singing at the same pitch in open singing. In open singing, the vocal cords are longer and thicker, the sinus Morgagni is smaller and the larynx is more raised. Thus both the external and the internal larynx muscles are more contracted in open singing than at the corresponding pitch in covered singing. In covered singing, there are fewer harmonics than in the corresponding open singing (Winckel, 1952; van den Berg *et al.* 1959; Gemelli *et al.* 1954; Sonninen, 1962, 1969; Large, 1969) i.e. the OQ must be smaller in open singing than in covered singing. Luchsinger observed that the air consumption is smaller in open singing than in covered singing. Taking into account also Ishikawa and von Leden's observations, it seems evident that in an open man-

ner of delivery in which the larynx muscles are greatly contracted and the air consumption is small, glottal resistance is greater than in the covered manner of delivery.

The above observations seem to support my hypothesis in every way. The open-voice mechanism resembles my example Case B and the covered-voice mechanism Case A. In the more primitive open-voice mechanism, voice strain is directed above all to the vocal ligament. When the injury to the ligament is great enough, the consequence is a secondary injury of the subepithelial tissue. Histological research has shown that in a vocal-cord nodule the epithelium is normal, and the changes occur in the subepithelial tissue. This appears to add further support to my hypothesis. It would be interesting to know if the primary changes in an incipient vocal-nodule case are to be found in the vocal ligament.

According to my hypothesis, the mechanism of an incorrect use of the voice injures the supporting tissue first. As it is known that collagen degeneration caused by mechanical trauma appears in degeneration of the intervertebral disc in the peripheral layer of fibrils, as a consequence of which there are reactive infectious changes in the surrounding tissue, the thought occurs whether in vocal-cord nodules, too, the primary cause could be collagen degeneration, a kind of "Tumbago laryngitis". Much additional research is, of course, needed before this kind of tentative hypothesis can be proved right or wrong.

In the foregoing I have dealt, principally as a phoniatrician, with some problems which are, to my mind, essentially connected with hoarseness. I would, finally, like to stress once again that hoarseness in itself is no simple concept, but that the problems connected with it should be dealt with on at least the four levels I have presented here.

What, then, is the mechanism of the kind of voice strain which first injures the subepithelial tissue? Friction hardly comes into the question.

At the conference organised by the New York Academy of Sciences in 1966 the subject under discussion was, "The external frame function in the control of pitch in the human voice". On the basis of my investigations, I formulated a hypothesis according to which "vocal nodules develop chiefly as a result of excessive loading on the tensor ligaments in incorrect open-voice singing". According to this theory the most important element is the injury of the vocal ligament itself, not the injury of the subepithelial tissue or of the muscular fibrils. I would now like to present this theory of mine in somewhat greater detail.

From high-speed films we know that the upper margin of the vocal cords and the vocal ligament rotate and that the rotating vibration amplitude is greatest at the junction of the anterior and middle thirds of the cord. As the voice rises the vocal ligament is tightened and the movement becomes smaller and faster. At the same time the vocal ligament lengthens.

Case A Let us imagine a vocal ligament which has a certain tension, and mass, as a piece of string of a certain length. When the wind moves this piece of string its speed of vibration is F_1 (Fig. 1).

Case B The piece of string is tightened, so that the tension increases. Its length becomes greater, the vibration amplitude decreases, and the vibration frequency increases ($F_2 > F_1$). If a suitable amount of additional mass is added to this tightened piece of string the vibration frequency reverts again to the Case A frequency ($F_2 = F_1$) but the tension, the length, and the mass in Case B are still greater than in Case A. My hypothesis is as follows: the tightened and loaded piece of string will break sooner than the string in Case A, although both have the same vibration frequency.

We know that the vocal-cord muscles have anatomical possibilities of increasing the mass of the vocal ligaments when contracted. This

Fig. 1 Two possible habits of vocal ligament vibration: Case A, correct and Case B, "incorrect". The tightened and loaded vocal ligament (Case B) will "break" sooner (resulting in vocal nodules) than the vocal ligament in Case A, although both have the same vibration frequency.

presumably explains the irregularities of the vocal-cord vibrations that appear in tonus disorders of the muscle. It is not really of great importance whether the muscular fibrils are directly attached to the vocal ligament or not. The most important thing is that connective tissue fibrils from the vocal ligaments protrude between the fibrils of the thyroarytenoid muscles, which makes it possible for the muscular tissue as it contracts, to engage its own mass in the vibratory movements of the vocal ligament to the same extent as the muscular fibrils contract. Let us think of the vocal ligament as a boat rocked by the sea. Someone on the jetty need not hold on to the boat with his hand. If there is a string leading from the man standing on the jetty to the boat and the string is loose, the boat rocks freely. If the string is tightened, the boat begins to pull with a rocking rhythm at the person who is tightening the string, and at the same time the movement of the boat itself subsides.

The vocal cords are slack and short when the voice is low. They tighten and lengthen as the voice rises right up to the moment when

DISCUSSION

J. Paiva. I should like to put a question to Doctor Sontinen, or any other phoniatrician present, as to the development of vocal nodules. It is important to have various theories, but the medical aspect of the problem should always be remembered and an explanation be sought for. About six months ago it was reported in *Laryngoscope* by two American colleagues that vocal nodules can be caused by the acid fluid coming into the mouth and spilling over the arytenoids and posterior parts of the vocal cords in peptic oesophagitis. The nodules disappeared after antacid therapy. Nodules were also produced experimentally in dogs by applying acid fluid to the vocal cords.

A. Sontinen (Reply to Paiva). We can have many "aetiological" factors concerning vocal nodules. In my opinion, it is not possible to leave out mechanical interpretations which can only explain why vocal nodules have the localization in the vocal cords they have (conjunction of anterior-middle third).

DISCUSSION

T. Palva. I should like to put a question to Doctor Sonninen, or any other phoniatrician present, as to the development of vocal nodules. It is important to have various theories, but the medical aspect of the problem should always be remembered and an explanation be sought for. About six months ago it was reported in *Laryngoscope* by two American colleagues that vocal nodules can be caused by the acid fluid coming into the mouth and spilling over the arytenoids and posterior parts of the vocal cords in peptic oesophagitis. The nodules disappeared after antacid therapy. Nodules were also produced experimentally in dogs by applying acid fluid to the vocal cords.

A. Sonninen (Reply to Palva). We can have many "aetiological" factors concerning vocal nodules. In my opinion, it is not possible to leave out mechanical interpretations which can only explain why vocal nodules have the localization in the vocal cords they have (conjunction of anterior-middle third).

JUDGING THE MOVEMENTS OF VOCAL CORDS IN LARYNX PARALYSIS

S Fax

From the Department of Otolaryngology University Hospital Lund Sweden

In paresis of the recurrent laryngeal nerve the homolateral vocal cord cannot adduct or abduct, but some of the phonatory movements can still be seen in stroboscopic light or on the high-speed film. A discussion of the conclusion which can and also of those which cannot be drawn from the return of the missing phonatory movement of the paretic vocal cord the glottic wave is presented.

The larynx has a number of different functions of which the respiratory and the phonatory ones are the most important. It is essential for respiration that the vocal cords can be abducted in order to be out of the way for the air stream and that they can be adducted in coughing. For phonation the vocal cords have to be adducted. Paralysis of both recurrent laryngeal nerves results in the cessation of the respiratory movements, but if the vocal cords are immobilized sufficiently close to each other phonatory movements can still occur.

Normally the most important phenomena of the phonatory movements of the vocal cords are of two kinds which can be seen by means of a high-speed film or simpler and thus more practical by the aid of a laryngeal stroboscope. One of these phenomena concerns the amplitude of the vibrating vocal cord and is, among other things, dependent on the tonus of the cord and is normally reflected in the volume of the given tone. The other one is the "glottic wave" (in German: "Randkantenverschiebung"). This phenomenon was first registered in the famous Bell film of 1938 but was first studied closely by Svend Smith in the mid fifties. He showed in brilliant model experi-

ments that a glottic wave could be obtained only if the superficial layer and the large mass of the vibrating body were of different consistency. At phonation in normal speech tone, the musculature in the healthy vocal cord is more or less actively contracted which, of course, does not go for surrounding tissues, and a glottic wave can also be seen. If phonation is made at high frequency especially in falsetto the musculature of the vocal cord is only slightly contracted, or not at all. From a vibratory point of view the vocal cord then consists of a homogeneous mass which has a passive tonus, as stressed by Damsté (1968), i.e. the attachments of the vocal cord are removed from each other by contraction of the cricothyroid muscle, and a glottic wave cannot be seen.

Loss of the cricothyroid function causes small qualitative changes in the mobility of the vocal cords, but it has been known for a long time that if paralysis of the recurrent laryngeal nerve develops, the glottic wave of the homolateral vocal cord disappears, and it seems reasonable to assume that this is because the vocal cord loses its own tonus and becomes homogeneous from a vibratory point of view. Another phenomenon which is also found in paralysis of the recurrent laryngeal nerve is a side difference in amplitude where the paralyzed vocal cord can show a stronger as well as a weaker deflexion than the healthy one.

It is, however the loss of the glottic wave

and, especially the judgment of the return of it which belong to the interesting things in paralysis of the recurrent laryngeal nerve. It is well known and is probably best described by Schönhlir in his book on stroboscopy of 1960 that the return of the glottic wave is the first sign of a recovering paralysis of the recurrent laryngeal nerve. It is thus usually possible to see in stroboscopic light a glottic wave one or a few weeks before mobility of the cord can be seen in ordinary light. Undoubtedly it is true that if a recurrent paralysis recovers completely the return of the glottic wave is the first sign, but the opposite, viz. that a returning glottic wave also signifies the return of abduction is not absolutely certain. If a recurrent laryngeal nerve is injured seriously enough to degenerate, there is from a neurophysiological point of view no reason to assume that on regeneration the nerve fibres are going to reinnervate the same muscle fibres or the same muscles as before. On the contrary there are good reasons to suppose that reinnervation will occur randomly so that in one and the same muscle there will be mixed nerve fibres which normally cause contraction at inspiration, i.e. of the abducting muscle, and others which normally cause contraction at expiration, i.e. have an adducting function. This mixed innervation has been shown electromyographically by Hiroto et al. (1968) and is presumably what Faaborg-Andersen (1964) had observed when he called attention to the fact that many vocal cords immobilized by paralysis of the recurrent laryngeal nerves still showed reinnervation potentials. However such an irregular reinnervation will also give rise to at least some muscular tonus, and this is probably the

explanation of what can occasionally be seen when a patient with paralysis of a recurrent laryngeal nerve reveals a discrete glottic wave for a period of up to several weeks, but without the expected increasing mobility seen in ordinary light. On such occasions innervation has returned, but function has not, and it seems likely that a relatively considerable number of patients with non-recovering paralysis of recurrent laryngeal nerves consist of such cases. It should therefore be correct to entertain a cautious optimism if you in a patient with a recurrent nerve paralysis find a returning glottic wave in the paretic vocal cord, but you cannot at the sight of such a glottic wave abandon additional control of the mobility of the vocal cord and the patient's voice until further assurance of the final result has been gained, as the glottic wave can only give information of the tonus in the muscle of the very vocal cord at phonation. It is not at all possible to draw conclusions as to the innervation of the same muscle at inspiration, nor as to other laryngeal muscles as a whole.

JUDGING THE MOVEMENTS OF VOCAL CORDS IN LARYNX PARALYSIS

§ Fex

From the Department of Otolaryngology University Hospital Lund Sweden

In paresis of the recurrent laryngeal nerve the homolateral vocal cord cannot adduct or abduct, but some of the phonatory movements can still be seen in stroboscopic light or on the high-speed film. A discussion of the conclusion which can, and also of those which cannot be drawn from the return of the missing phonatory movement of the paretic vocal cord, the glottic wave is presented.

The larynx has a number of different functions of which the respiratory and the phonatory ones are the most important. It is essential for respiration that the vocal cords can be abducted in order to be out of the way for the air stream and that they can be adducted in coughing. For phonation, the vocal cords have to be adducted. Paralysis of both recurrent laryngeal nerves results in the cessation of the respiratory movements, but if the vocal cords are immobilized sufficiently close to each other phonatory movements can still occur.

Normally the most important phenomena of the phonatory movements of the vocal cords are of two kinds which can be seen by means of a high-speed film or stroboscope and thus more practical by the aid of a laryngeal stroboscope. One of these phenomena concerns the amplitude of the vibrating vocal cord and is, among other things, dependent on the tonus of the cord and is normally reflected in the volume of the given tone. The other one is the "glottic wave" (in German "Randkantenverschiebung"). This phenomenon was first registered in the famous Bell film of 1938 but was first studied closely by Svend Smith in the mid fifties. He showed in brilliant model experi-

ments that a glottic wave could be obtained only if the superficial layer and the large mass of the vibrating body were of different consistency. At phonation in normal speech the musculature in the healthy vocal cord is more or less actively contracted which, of course, does not go for surrounding tissue and a glottic wave can also be seen. If phonation is made at high frequency especially falsetto the musculature of the vocal cord is only slightly contracted, or not at all. From a vibratory point of view the vocal cord thus consists of a homogeneous mass which has a passive tonus as stressed by Damsté (1961) i.e. the attachments of the vocal cord are moved from each other by contraction of the cricothyroid muscle, and a glottic wave can be seen.

Loss of the cricothyroid function causes small qualitative changes in the mobility of the vocal cords, but it has been known for long time that if paralysis of the recurrent laryngeal nerve develops, the glottic wave of the homolateral vocal cord disappears, and it seems reasonable to assume that this is because the vocal cord loses its own tonus and becomes homogeneous from a vibratory point of view. Another phenomenon which is also found in paralysis of the recurrent laryngeal nerve is a side difference in amplitude, where the paralysed vocal cord can show a strong as well as a weaker deflexion than the healthy one.

It is, however, the loss of the glottic wave

ELECTROMYOGRAPHY IN VOCAL-CORD PARESES

S. Haglund, E. Knutsson, A. Mårtensson and B. Mårtensson

*From the Departments of Clinical Physiology, Neurology and Otolaryngology
Karolinska Spital, Stockholm, Sweden*

A recently developed electromyographic recording technique usually permitting identification of about 20 individual motor-unit potentials from each vocal muscle has been utilized in some cases of traumatic recurrent nerve palsy. As an adjunct to the ordinary routine clinical examinations, this method seems to be useful in cases in which prognostic evaluations are uncertain owing to difficulties in assessing the lesion present.

In the course of a series of investigations of the electromyographic activity in vocal-cord paresis it proved to be difficult in many cases to determine to what extent the recorded motor-unit potentials deviated from normal, since no reliable data were available on the activity pattern in the normal vocal muscle. It has previously only been possible to identify a small number of individual motor-unit potentials from each muscle. In a paper to be published (Knutsson *et al.* in press) a recently developed method usually permitting identification of 20 motor-unit potentials from each muscle has been described and data presented on the electromyographic activity in the normal vocal muscle, as based on an analysis of the shape, duration and amplitude of 469 motor-unit potentials from 18 muscles.

The method has now been applied in examinations of patients with various types of disturbed vocal-cord motility among them seven cases of traumatic recurrent-nerve lesions, and as will appear from the three illustrative cases presented below it has been possible by means of this new technique and the data recently assembled on the normal electro-

myographic pattern, to assess significant deviations relevant for prognostic evaluations.

Since a full description of the techniques employed will be presented in the paper now in press, only a few principal details will be given below.

For the recordings, a conventional ENG needle is used which is inserted through the cricothyroid membrane at the midline, just above the cricoid cartilage. The vocal cords are brought into an adducted position by requesting the patient to hold his breath after an inspiration, and the needle is then further advanced after being angled axially upwards and slightly laterally. As soon as the electrode makes contact with the vocal cord, change in the electrical resistance at the tip is displayed on the oscilloscope screen. The needle is then pushed approximately 1 cm further into the muscle and the recordings performed under gradual withdrawal and rotation of the electrode.

Routinely, try to record some 20 of the motor-unit potentials set up spontaneously during quiet breathing (Weddell *et al.*, 1944), and these potentials are photographed for subsequent analysis. The activity during deglutition and phonation is also recorded at one or three different points in each muscle. In normal subjects, these activations result in typical interference patterns which in cases of extensive denervation undergoes characteristic changes (Fasborg-Anderen, 1957).

The recordings are performed under local anesthesia of the skin at the site of needle insertion and of the subglottic mucosa and can usually be terminated in about 15 minutes. During the first hours after the examination the patients may experience a slight irritation in the larynx and develop some hoarseness, which, however, invariably subsides within 24 hours. No other untoward effects were observed in about 50 examinations so far performed.

Case 1 was a 26-year-old man, operated on for a branchiogenic cyst of atypical localization in the neck. The recurrent nerve had to be

PALATAL MUSCLE ACTIVITY AND VELAR
MOVEMENTS IN SPEECH

B Fritzell

*From the Division of Phoniatrics, Department of Otolaryngology, University of Göteborg,
Göteborg, Sweden*

This study was made to provide electromyographic information on the discrete activity of the individual palatal muscles in speech and some non-speech activities. Specially designed monopolar needle electrodes were inserted transnasally and very thin wire electrodes transorally into the levator tensor superior constrictor and palatoglossus, palatopharyngeus muscles, respectively. Cine-radiography was carried out

during EMG-recordings from the levator and palatoglossus muscles. Levator activity was closely related to velopharyngeal closure and palatoglossus activity to lowering of the velum. Some intensity and time relationship are analysed and the results are presented.

(Published in Acta Oto-Laryngologica, Suppl. 258, 1969)

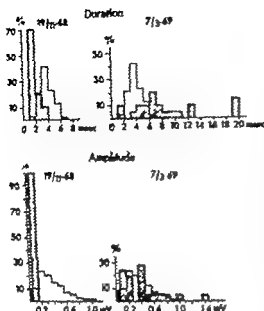

Fig. 1 Duration and amplitude distribution of motor unit potentials recorded from vocal muscle in Case 3 (shaded columns) on two occasions, showing different stages of motor distribution, as compared with corresponding data from the normal material (white columns).

were denervation potentials. In this case it was anyhow possible to establish that a partial denervation had occurred since there was evidence of regeneration. As appears from the histogram, more than 30 % of the potentials have a duration exceeding 6 msec: this incidence is much higher than in the normal material. All these potentials except one as well as some potentials of shorter duration, totalling 40 % were polyphasic and of relatively low amplitude. The incidence of polyphasic potentials in the normal material is only 5 % in single individual cases up to 15 %. Judging from the electromyographic recordings, re-innervation was in progress, and the prognosis should thus be favourable. Ten weeks after operation, i.e. after another six weeks, the vocal cord had in fact resumed normal motility the voice being in the patient's opinion of the same strength as pre-operatively.

Case 3 illustrates a considerably more delayed re-innervation in a 65-year-old patient who due to disturbed heart rhythm after a myo-

cardial infarction had had a pacemaker applied and on this occasion, in an emergency situation, the left vagus nerve was apparently injured. Owing to his poor general condition it was not observed that he was hoarse until two months after operation, and laryngoscopy was not performed until after another seven months. The left vocal cord was then found to be immobile in the paramedian position. EMG recordings were performed from the paretic muscle, and the duration and amplitude of the potentials found are plotted on the left-hand side in Fig. 3. A few single motor-unit potentials were set up during deglutition, but most of the potentials had features characteristic of fibrillation potentials. The electromyogram thus disclosed a pronounced denervation, but no total interruption of the nerve. Four months later the vocal cord was still paralytic, but the electromyogram was then quite different, as is evident from the histograms on the right-hand side of Fig. 3. The amplitude distribution was now similar to that in the normal material, but most of the potentials had a duration far above normal values. Although the incidence of polyphasic potentials was not significantly higher than in the normal material, the increase in duration was considered indicative of progressive re-innervation, an assumption that was confirmed a month later when the clinical examination disclosed incipient motility of the vocal cords, and the voice had also improved.

DISCUSSION

F. Peytz and H. Rasmussen: In the Finsen Institute, Copenhagen, we have performed studies with stimulation of the vagus nerve and its

Fig. 1. Duration and amplitude distribution of motor unit potentials recorded from vocal muscle in Case 1 (hatched columns) as compared with corresponding data from the normal material (white columns).

dissected free on the left side. Although no lesion was observed at operation the left vocal cord was postoperatively immobile in the paramedian position and was still paralytic three weeks after operation. EMG recordings from this period disclosed only diffuse potentials of low amplitude, indicating pick up of activity from nearby muscles, e.g. the cricothyroid. As judged from laryngoscopic inspection, the vocal cord had resumed normal motility four weeks later and the voice appeared to be normal. At this time, the electromyographic activity during deglutition showed no interference pattern and only sparse motor unit potentials. Eighteen potentials were identified, the duration and amplitude distribution of which appears from the histograms in Fig. 1 (hatched columns) in which for comparison also corresponding data on the 469 potentials from 18 previously analysed normal muscles are included (white columns). In this case the relative number of potentials of a duration less than 2 msec. is considerably larger than in the normal material as is also the incidence of potentials of an amplitude below 0.15 mV.

All low amplitude potentials were of short duration although this does not appear from the histograms. They should thus be regarded as fibrillation potentials, indicating a denervation. Since, however, a large proportion of the potentials fall within normal limits both as regards duration and amplitude, the interruption of the nerve should only be partial and prognostically full recovery can be expected.

Case 2 was a 50-year-old man with an immobile left vocal cord following strumectomy due to an atoxic adenoma. Four weeks after operation the vocal cord was still immobile. EMG recordings performed at this time disclosed that only a few single motor-unit potentials were set up on activation by deglutition. The histograms in Fig. 2 illustrate the duration and amplitude distribution of 20 identified potentials as compared with normal values. As seen 15% of the potentials have a duration of 2 msec. or less. In the normal material, the incidence of such brief potentials is much lower but since single individual normal muscles may occasionally display a similar incidence (Knutsson *et al.* in press) it is not justifiable to draw the conclusion that these brief potentials

DISCUSSION

F. Peytz and H. Rasmussen. In the Flinck Institute, Copenhagen, we have performed studies with stimulation of the vagus nerve and its

branches since 1963. The technique, which was devised in collaboration with Professor Buchthal and was published in the Danish Medical Bulletin in 1965, is briefly as follows. Electrodes are inserted percutaneously and para-tracheally 2.5 cm below the cricoid cartilage for stimulation of the recurrent nerve and at the same level behind the sternocleidal muscle for stimulation of the vagus nerve and in front of the vascular sheath at the level of the hyoid bone for stimulation of the superior laryngeal nerve. Electromyography is performed simultaneously with electrodes in the muscles concerned, i.e. percutaneously in the cricothyroid and by direct laryngoscopy under local or general anaesthesia in the vocalis and in the posterior cricoarytaenoid muscle.

We have studied about 270 patients—some of them repeatedly and in several cases bilaterally. Among the 270 patients, paresis of the recurrent nerve was present in about 100 while the remaining patients were normal or were examined for laryngeal cancer or neuromuscular disorders, or were studied during thyroid operations with a view to localization of the recurrent nerve. About one half of the patients with paresis of the recurrent nerve were studied within the first 6 months after the occurrence of the paresis, the earliest examination being performed 4 days after the onset. The remaining cases were of longer duration; the oldest case had persisted for 32 years. The two largest groups were post-strumectomy pareses and pareses of unknown aetiology. Other groups were, for example, malignant lesions of the neck or lungs, and so-called central pareses.

From our studies we conclude that in paresis of a duration of up to 6 months a response of normal amplitude and with normal conduction time is suggestive of a favourable prognosis. The earlier a response is obtained and the more it approaches normal with regard to amplitude and conduction time, the better is the prognosis. However, caution should be exercised in the assessment of the response as fairly wide variations seem to exist. So far our knowledge is limited, but we hope that in the study of a sufficiently large number of cases it will be possible to reveal definite prognostic signs by means of this method.

S Fex: Did you do registrations also at inspiration? From a prognostic point of view it would be of value to know if what Srimodhi *et al* called "misdirected fibres" has been the reason for unphysiological re-innervation, i.e. abnormal function.

S Haglund (Reply to Fex): It has been possible without difficulty to keep the electrode in a stable position to permit recordings from single motor units during repeated respiratory phases. In some units, the discharge frequency was comparatively stable, whereas, in others, the frequency varied with respiration. Some of these units fired only during one of the respiratory phases.

Therefore, from pathological cases with signs of re-innervation it does not seem possible to draw a conclusion of misdirected fibres in this way; it has been done in the paper by Hirose *et al*.

ELECTROMYOGRAPHIC STUDIES OF THE FUNCTION OF THE FACIAL MUSCLES IN DYSPARTHIA

R. Leanderson, A. Persson and S. Olman

*From the Department of Otolaryngology and Central Neurophysiological Laboratory
Karolinska Hospital, Stockholm Sweden*

The EMG activity picked up by needle electrodes from six facial muscles, mainly responsible for the labial articulation, was recorded simultaneously with the speech. Through repeated detailed studies on one speech-trained subject and analytic comparison between several individuals in normal articulation, we have gained knowledge of the normal neuro-motor activity of the muscic musculature during speech. In this paper we present the common characteristics of the EMG speech pattern of normal speakers compared with that of patients with organic dysarthria.

Relatively few experimental studies have been made on the function of the facial muscles during speech. It was not until the beginning of the 1960's that a group of phoneticians at the Haskins Laboratories in New York started to use the electromyographic technique in their studies of speech to find a neuromuscular pattern for linguistic elements and speech gestures. They used mainly surface electrodes. But if

we want to study simultaneously the reciprocal innervation of the muscles and the muscle co-ordination indispensable to fluent speech, it is necessary to use needle electrodes, because of the topographically complex anatomy of the muscles around the lips. Properly placed, these electrodes will give satisfactory functional separation.

Articulation disturbances caused by organic diseases in the nervous system of the speech organs, dysarthria, have so far been studied mostly clinically by subjective auditive and visual assessment and experimentally by objective spectrographic analysis. By interdisciplinary phonetical, neurophysiological and phonotrical co-operation we have developed a method of examination and identified the particular electromyographic pattern of the individual normal-speaking person and found

ELECTRODE POSITIONS

Fig. 1

Fig. 1.

characteristic EMG features common to the entire normal group

Against the background of these observations we then studied the movements of lip articulation in a group of patients with Parkinson's disease and dysarthria. A comparative analysis showed that several deviations in the EMG pattern were common to this group

Fig. 1 shows the electrode positions used in nearly all the studies. The investigated muscles were the levator labii (LLS), the orbicularis superior (OOS) and inferior (OOI), the depressor anguli (DAO), the depressor labii (DLI), and the mentalis (M). They were chosen in explorative studies of all the functional muscle units in the facial region. The technique used in finding the optimal needle position is described in the Proceedings of our Scandinavian Congress in Helsinki, 1966, in which the phonetic material for the movements of articulation is also presented. The EMG activity was recorded simultaneously with speech on a multi-channel tape-recorder and traced on a polygraph or an EEG apparatus.

The prerequisite for fluent speech is a well-learned neuromuscular speech pattern. This is individual, and under standardized experimental conditions and with a suitable phonetic material it is well reproducible at repeated investigations.

Fig. 2 shows a series of V_1CV_2 (vowel-consonant-vowel) combinations placed in a constant linguistic frame. $C = /p/$ and the vowels, which change place throughout, are $/i/$, $/u/$ and $/y/$. An analysis of the EMG activity of the relevant facial muscles recorded simultaneously with speech shows the following features.

Muscle function during speech consists partly of a basic tonus, which has also been found, for instance, in chest and palate muscles and which we call speech posture, partly of a manipulatory activity. The initial position of the muscle muscles is influenced by a variety of factors—we smile, are sad, tense, relaxed, and so forth. The manipulatory activity is much faster and produces the different single sounds. The postural activity is found in the

levator and depressor labii and the manipulatory activity mainly in the orbicularis and depressor anguli. This functional distribution is very striking and indicates that the facial muscles contain both tonic and phasic components.

As labial articulation movements the EMG tracings of the activity of the perioral muscles show normally a well co-ordinated excitation and inhibition, respectively of the different muscle groups that act synergistically or antagonistically. The activity in a muscle for a particular sound depends on the position of the lips and the activity of the muscle during the preceding sound (see $/i/$ or $/y/$ after $/p/$ or $/p/$ after $/y/$ and $/i/$ respectively). The neuronal instruction to the facial muscles is, for instance different for an $/i/$ depending upon whether the preceding lip movement is rounded or spread. This fact gives rise to questions concerning the afferent flow of impulses. What type of muscle receptors occur? What part do skin and mucosal sensation play? Of what significance is auditive feed-back?

If muscle spindles occur they are very few and would not play any predominant part. We have started studies with masking of hearing and various types of anaesthesia of the trigeminal nerve. We are also planning to investigate patients with trigeminal neuralgia after nerve block and root section.

The EMG activity starts before the sound is heard, and this interval varies for different sounds and for the same sound in different positions, for instance for a vowel, depending on whether it is preceded by a labial or a non-labial consonant (cf. $/y/$ as V_1 with $/i/$ as V_2 after $/p/$). The onset of activity for a consonant is dependent of the foregoing vowel (see $/p/$ after $/i/$, $/y/$ and $/u/$ respectively). The EMG activity of a rounding or spreading movement for a vowel that is not preceded by a labial consonant starts about 200 msec. before the sound is heard, but about 80 msec. after a labial stop like $/p/$. The EMG activity for $/p/$ appears 10 to 15 msec. earlier after $/i/$ than after $/y/$ and even later after $/u/$. (The lip position of $/u/$ is very near to that of $/p/$)

Fig 3

The implosion phase and the release phase of a normal stop consonant are very well co-ordinated. If the succeeding vowel is spread, the vowel command coincides with the release activity which will then appear earlier.

The EMG pattern is constant in one and the same subject. In one of our subjects we made at least some ten studies on different occasions with reproducible results.

Variations occur between subjects, particularly of quantitative nature and with respect to basic tonus—"speech posture"—from complete relaxation between utterances to continuous tonic activity on which the manipulatory activity is then superimposed in both excitation and inhibition. Studies of a group of normal speakers have demonstrated common EMG characteristics. These then served as material for comparison in studies of patients with organically conditioned disturbances of articulation.

Fig 3 shows a comparison between normal articulation and dysarthria in Parkinson's disease. The patient's EMG pattern shows a generally markedly increased tonus, notably in the muscles responsible for the postural activ-

ity the levator labii and the depressor labii. This pathological hypertonia does not allow the manipulatory excitation and inhibition activity which is seen in the normal speaker even at increased basic tonus.

The normally well co-ordinated and properly balanced synergistic-antagonistic function is upset. Not only do all the muscles function simultaneously and inadequately but there is also an increase in antagonistic activity instead of a decrease (the levator labii, which is really an /s/ muscle becomes just as active for /h/ when it should stop functioning).

Normally the onset activity for a sound decreases throughout the continuance of the sound, and if a spread vowel is preceded by a similar vowel, no new activity is seen. In the patient we find that the activity lasts longer and that it is renewed for a similar sound. The onset activity period i.e. the period by which the EMG activity precedes the sound, is also longer. This long-lasting activity can interfere with and sometimes prevent the production of a new sound and result in a kind of perseveration (/ypi/ becomes /ypyi/).

Normally there is a difference of 20 per

cent in EMG activity as regards both the closing and the opening phase for /p/ and /b/ respectively. With the higher intra-oral pressure at the voiceless /p/ with abducted vocal cords the lips must be closed more firmly but, in compensation the opening of the lips is easier. The voiced /b/ with the glottis closed has normally a lower intra-oral pressure, the lip closure needs less muscular activity but the lip opening must be more active than for /p/. This difference is not found in patients.

Fig. 4 shows a comparison of two patients. One (to the left) has been ill for a short period and has only slight dysarthria. Muscle hypertonia is more marked in the other patient and lip movements are stiffer, manipulatory activity is slower and becomes increasingly weaker. Co-ordination, in particular is impaired. The individual sounds can be produced one by one but not in the rapid sequence required in fluent speech, and so the patient's speech becomes indistinct and unintelligible.

Fig. 5 shows two EMG tracings from the same patient at an interval of six months. On the second occasion, the basic tonus has increased in all the muscles, notably in those with mainly postural function, the depressor labii and the levator labii. The balance between synergists and antagonists is also further upset. Instead of reducing its activity during the closing phase for /p/ the depressor labii now acts in the opposite way.

The function of the afferent mechanisms normally essential to fluent co-articulation must be disturbed in these patients. By continued studies of normal speakers and of patients, on the basis of what is already known of the pathophysiology of Parkinson's disease and from

other viewpoints, we hope to obtain further data on these mechanisms.

EMG studies of the facial muscles during speech provide the phonetician with important information as a complement to acoustic phonetics. They are also of neurophysiological interest by allowing the study of a complicated muscle function which is stereotypically automated and reproducible. They are, however, of particularly great importance in phoniatrics as a means of studying both organic and functional disturbances in articulation.

INFLUENCE OF THE NOSE ON THE ACOUSTIC PATTERN OF NASAL SOUNDS

J Kytölä

From the Department of Otolaryngology University Hospital, Turku, Finland

After changing the conditions in the nose on one or both sides, an attempt was made to ascertain the influence of these changes on the formation of the nasals *m* and *ng* both by auditory perception and by spectrographic methods¹. Complete closure of one side did not cause any change in the auditory perception of the nasals. However the decrease in, or disappearance of, energy in the higher-frequency areas can be established in the sonograms. Complete closure on one side and partial closure on the opposite side cause changes as follows: As long as the lowest nasal cavity is free, the epipharyngeal-nasal cavity formation, which is apparently formed primarily in this area, remains unchanged, i.e. at 250 cps. This is the most important frequency area of the nasals. If the lowest—and only—nasal cavity is closed, the higher frequencies will be intensified, and auditory perception receives plosive characteristics; if complete closure is brought about, the plosives get corresponding plosive structure. Individual variations are very wide in the formation of the nasals.

The Finnish nasal sounds *m*, *n* and *ng* are formed by using the lip the tongue and, above all, lowered velum and nasal cavity. According to the pronouncing place *m* can be characterized as a labial nasal, its corresponding plosives being *b* and *p*; *n* as a dental nasal, its corresponding plosives being *d* and *t*; *ng* as a palatal nasal, its corresponding plosives being *g* and *k*. The acoustic relationship of these is shown in Fig. 1 III which the sonagram has been presented schematically.

In regard to their acoustic structure the nasals, however resemble most of all vowels, even

though the vowel formants proper i.e. for mants of the pharyngeal cavity and oral cavity are in a less important position. The so-called formants (F 1 F 2, F 3 F 4 etc.) are harmonics or groups of harmonics reinforced in the resonance cavities of the vocal tract.

Further it is to be observed that nasalization is rather the rule than the exception in vowels which are situated near a nasal consonant or between them (Björk, 1961 Fant, 1968). In brief the following three factors may be mentioned as the characteristic features of a more or less nasalized vowel (Fujimura, 1958):

- 1 Intensity growing in the area of 250 cps.
- 2 Intensity weakening in the area of about 500 cps.
- 3 Appearance of comparatively weak and diffuse components between the vowel formants in the area of 1000-2500 cps.

In the Finnish nasals the energy concentrations, the formants or components are as follows (Sovijärvi, 1959 1961 Yipjö & Sovijärvi, 1962 Kytölä, 1965)

FN 1 = formant of the epipharyngeal cavity	200-250 cps
FN 2 = formant of the epipharyngeal cavity	1300-1600 -

Formants of the lower (inferior), middle (median) and upper (superior) nasal passage respectively:

FN 3 inf.	1930-2300 cps
FN 3 med.	2300-2700 -
FN 3 sup.	2700-3300 -
F 4	3300-3450 -

1 The so-called spectrograph "Sonograph" was used for the analysis of the physical quality of nasals. The Sonograph was described in greater technical detail by Power et al. (1947) and Fant (1968).

According to Fant (1968) *n* voiced occlusive nasal (nasal murmur) is characterized by a spectrum in which F 2 is weak or absent. A formant at approximately 250 cps generally extending into adjacent vocalic segment predominates the spectrum but several weaker high frequency formants (not always seen in spectrograms) occur one typically at 2200 cps. These higher formants are generally weaker than for laterals. The bandwidths of nasal formants are generally larger than in vowel like sounds.

The vowel formants proper are of secondary importance in the nasals. F 1 is found to be 300–430 cps, F 2 500–1900 cps and F 3 1800–2600 cps. The nasal *m* lacks a third formant because of the bilabiality of this sound.

Being vowel formants proper F 1 and F 2 are of secondary importance in the nasals themselves, but perform a definite transition decisively influencing the acoustic pattern of the preceding and following vowels. Thus, the initial *m* during the transition to the following vowel causes an upward glide of F 1 and F 2, whereas the medial *m* causes the opposite phenomenon in the preceding vowel. The initial *n* causes shifting of F 1 upwards, and of F 2

downwards, if the F 2 of the vowel that follows *n* permits this. When *n* is in medial position, the F 1 of the preceding vowel falls and F 2 rises subject to the above condition as regards F 2. In the case of *ng* approximately the same phenomenon occurs as in the medial *n* but is often less distinct because the F 1 area is broader than above. Thus, if one covers the nasal sound in the sonagram, it is possible, in the transition phase of the F 1 and F 2 of the preceding or following vowel, to say which of the nasals is concerned in each case. F 3 is not affected by the proximity of a nasal (Figs. 1 and 2).

In addition to the formant transition and formant resonances playing an essential part in the acoustic identifiability of the nasals, there is also another phenomenon, characteristic of the nasals alone and directly contrasted with the formant resonances. This is the anti-resonance produced by the oral cavity. Fant (1960) stated, "The effect of the mouth cavity as a side chamber shunting the sound transmission through the pharynx-nose system, is to cause a shift of resonance frequencies and to introduce anti-resonances. It has been verified by supplementary analog experiments that an increase of the coupling area to the mouth cavity as in the case of an incomplete lowering of the velum or a lowered tongue position, shifting the mouth cavity anti-resonance up to 100 cps, causes a neutralization of the 1000 cps nasal formant." Anti-resonance can be observed as "gaps" which become very prominent, especially in sections (Fig. 2). By changing the conditions in the nose (e.g. with a piece of cotton dipped into sodium chloride), it is at first seen that complete closure on one side does not cause a change in the auditory perception. In the sonagram one observes a general weakening of energy in the higher frequencies (Fig. 3 B). Thus, even bad septum deviations on one side, hypertrophic conchae or polyp have no considerable influence upon the acoustic pattern of the nasal.

If after this, changes are caused in the nose passage

Fig. 1 Spectrographic patterns illustrating the transition cues for the stop and nasal consonants in the initial position with the vowel *a*. The dotted portions in the second row indicate the presence of noise (aspiration) in this place of harmonics. After Liberman (1957).

Fig. 2. Spectrographic analysis of the anti-resonances found in nasals and appearing in the sections as "gaps". It is seen that the gap is broadest in the labial *m*, narrower in the alveo-dental *n*, and narrowest in the dorso-velar *ŋ*.

completely closed—it is observed that the glottal-pharyngeal-nose cavity formant remains at 250 cps as long as the lowest nose passage is free, and even becomes stronger if there is an obstacle in the middle or upper passage of the nose. The resonance of the upper nose pas-

sages is either missing or becomes weaker, more diffuse and similar to noise in the sonagram (Fig. 3 D). The phenomenon is opposite if the lowest passage of the nose is closed (Fig. 3 E). If one further continues the experiments with closure of the nose, so that the nose pas-

Fig. 3. Spectrographic analysis of the nasal sound *n*. A, the nose is completely open; B, one side of the nose is closed; C, the nose is completely closed; D, one side of the nose and the upper passages of the other side are closed; E, one side of the nose and the lowest passage of the other side are closed.

According to Fant (1968) m voiced occlusive nasal (nasal murmur) is characterized by a spectrum in which F 2 is weak or absent. A formant at approximately 250 cps generally extending into adjacent vocalic segment predominates the spectrum, but several weaker high-frequency formants (not always seen in spectrograms) occur one typically at 2200 cps. These higher formants are generally weaker than for laterals. The bandwidths of nasal formants are generally larger than in vowel-like sounds.

The vowel formants proper are of secondary importance in the nasals. F 1 is found to be 300–430 cps, F 2 500–1900 cps, and F 3 1800–2600 cps. The nasal m lacks a third formant because of the bilabiality of this sound.

Being vowel formants proper F 1 and F 2 are of secondary importance in the nasals themselves, but perform a definite transition, decisively influencing the acoustic pattern of the preceding and following vowels. Thus, the initial m during the transition to the following vowel, causes an upward glide of F 1 and F 2, whereas the medial m causes the opposite phenomenon in the preceding vowel. The initial n causes shifting of F 1 upwards, and of F 2

downwards, if the F 2 of the vowel that follows n permits this. When n is in medial position, the F 1 of the preceding vowel falls and F 2 rises subject to the above condition as regards F 2. In the case of ne approximately the same phenomenon occurs as in the medial n , but is often less distinct because the F 1 area is broader than above. Thus, if one covers the nasal sound in the sonagram, it is possible, in the transition phase of the F 1 and F 2 of the preceding or following vowel, to say which of the nasals is concerned in each case. F 3 is not affected by the proximity of a nasal (Figs. 1 and 2).

In addition to the formant transition and formant resonances playing an essential part in the acoustic identifiability of the nasals, there is also another phenomenon, characteristic of the nasals alone and directly contrasted with the formant resonances. This is the anti-resonance produced by the oral cavity. Fant (1960) stated "The effect of the mouth cavity as a side chamber shunting the sound transmission through the pharynx-nose system, is to cause a shift of resonance frequencies and to introduce anti-resonances. It has been verified by supplementary analog experiments that an increase of the coupling area to the mouth cavity as in the case of an incomplete lowering of the velum or a lowered tongue position, shifts the mouth cavity anti-resonance up to 100 cps, causes a neutralization of the 1000 cps nasal formant." Anti-resonance can be observed as "gaps" which become very prominent, especially in sections (Fig. 2). By changing the conditions in the nose (e.g., with a piece of cotton dipped into sodium chloride) it is at first seen that complete closure on one side does not cause a change in the auditory perception. In the sonagram one observes a general weakening of energy in the higher frequencies (Fig. 3 B). Thus, even bad septum deviation on one side, hypertrophic conchae or polyp have no considerable influence upon the acoustic pattern of the nasal.

If after this, changes are caused in the nose passage of the other side—one side being

Fig. 1 Spectrographic patterns illustrating the transition cues for the stop and nasal consonants in the initial position with the vowel a . The dotted portions in the second row indicate the presence of noise (aspiration) in the place of harmonics. After Liberman (1957).

Fig. 2. Spectrographic analysis of the anti-resonance found in nasals and appearing in the sections as gaps. It is seen that the gap is broadest in the labial *m*, narrower in the alveo-dental *n* and narrowest in the dorso-velar *ŋ*.

completely closed—it is observed that the glottal-pharyngeal-nose cavity formant remains at 250 cps as long as the lowest nose passage is free, and even becomes stronger if there is an obstacle in the middle or upper passage of the nose. The resonance of the upper nose pas-

sages is either missing or becomes weaker more diffuse and similar to noise in the sonagram (Fig. 3 D). The phenomenon is opposite if the lowest passage of the nose is closed (Fig. 3 E). If one further continues the experiments with closure of the nose, so that the nose pas-

Fig. 3. Spectrographic analysis of the nasal sound *a*. A, the nose is completely open; B, one side of the nose is closed; C, the nose is completely closed; D, one side of the nose and the upper passages of the other side are closed; E, one side of the nose and the lowest passage of the other side are closed.

sages are otherwise free, but the nostrils are closed it is observed that FN 1 formant rises up to 350 cps. If the obstacle is pushed deeper into the nose, it is observed that this formant rises further and when the midway to the septum has been reached, i.e. approximately 4 cm from the nostrils the formant rises up to 500–1000 cps, which is the same level as the anti resonance has. The nasalization stops and the nasal consonant in question changes into some other sound. In some cases, it may start to resemble the preceding or subsequent vowel or—which is most common—*m* gets the acoustic structure of *b* or *p* *n* that of *d* or *t*, and *ng* that of *g* or *k* as it was somehow to be expected and as was discussed in the beginning of this presentation when listing the corresponding plosives (Fig. 1).

In this connection, attempts have been made to ascertain the influence of the side cavities of the nose especially the most accessible of these, the cheek cavities, upon the nasalization. After filling first one of the cheek cavities and then the other with radio-opaque material (Djanosil) the consistency of which is comparatively thick, sonagrams were recorded, but no considerable changes were observed. It is apparent that the oral and nasal stress needed for normal

speech is so small that hardly any side cavity resonance appears the situation is different in singing or even perhaps in reciting, because the performer needs then a larger soundboard, and co-operation of the side cavities is necessary.

PROMINENT EARS

A TECHNIQUE FOR PLASTIC CORRECTION

H. Wæster

From the Department of Otolaryngology, University Hospital, Aarhus, Denmark

A technique for correction of congenitally prominent ears is described. The ear is brought into the natural position in relation to the head, and the anthelix and crura are reconstructed so that they appear well formed. The method utilizes the known spontaneous healing tendency of the auricular cartilage following scratching of the anterior surface of the cartilage. To bring the lower part of the ear and the lobe into the natural position, thinning of the caudal helix and auricular cartilage is used. The ear is kept in the desired position by making mattress sutures. A check-up of patients operated on by this method was performed.

Prominent ears is a congenital deformity which is often the cause of teasing, a constant source of humiliation and always an occasion for hints. In many cases, this deformity gives the physiognomy a queer, ridiculous expression, which may now and then give rise to psychic problems. Embryologically prominent ears is a deformity caused by a evolutionary anomaly of the mandibular arch and the hyoid arch of the first branchial groove. In rare cases, the cause can be an intra-uterine lesion, but in such cases the deformity is usually unilateral.

The external ear is developed about the sixth embryonic week and reaches its final shape about the third embryonic month. However the folding of the anthelix and crura anthelica is not accomplished until the sixth embryonic month.

The angle between the normally placed external ear and the skull (cephaloscapal angle) is about 30°. Seen from behind the angle between the concha and the skull is about 90° and will be almost the same for a normal ear

and a prominent ear. In normal ears, the angle between the concha and scapha is about 90° while in protruding ears this angle is greater than 90° (Fig. 1).

Review of Literature

In the literature numerous methods of correcting prominent ears are reported. Several of these are only of historical interest to-day. Some methods describe a conservative way of correcting the deformity. Tying the external ear to the skull for a certain period of time, and gluing the ear to the planum mastoideum have been

Fig. 1

suggested. These methods proved useless, due to the elasticity of the ear cartilage which remains unaltered in spite of a temporary change in position.

The first surgical correction of outstanding ears was described by Dieffenbach in 1845. He made an excision of the skin from the back of the external ear followed by suture of the cartilage to the periosteum of the mastoid. In 1881 Ely described a method with excision of the skin and cartilage through the entire thickness of the ear leaving a scar on the anterior surface of the auricle. A similar procedure was advised by Fishman & Fishman in 1946. To avoid scarring, Keen suggested in 1890 excision of the cartilage without cutting the skin on the anterior aspect of the ear. During the following years, several surgical procedures were described all with excision or incision of the cartilage, to break the elasticity of the ear cartilage (Monks, 1891; Haug, 1894; Joseph, 1896; Moresun, 1903; Goldstein, 1908; Kollé, 1911; Gersuny, 1903; Payn, 1906; Rutten, 1910).

All procedures on the cartilage were performed in the cephaloconchal angle in an attempt to reduce the angle and so bring the external ear nearer to the head without changing the anatomy of the ear. In many cases the cosmetic result was not very satisfactory, as the ear often came unnaturally near the head and the postauricular sulcus was not infrequently completely obliterated. In 1910 Lockett reported that these operations did not give a permanently good result, and that the normal anatomy of the ear was not reconstructed. Lockett realized that most outstanding ears were caused by a too large scaphoconchal angle because of a missing or badly developed anthelix. The conchal cavity continues into the scaphal fold without being divided by the anthelix fold. Lockett used excision of a crescent shaped piece of cartilage where he wanted the new anthelix to appear. The position of the ear was maintained by sutures through the perichondrium. In spite of the fact that many new surgical procedures have subsequently been described

the surgical principle utilized by Lockett is still the basis of most of the surgical methods of to-day. A disadvantage which the method of Lockett and its subsequent modifications have in common is that the outcome is often an unnaturally sharp and edged anthelix. To avoid this disadvantage, Brown (1938) suggested to thin the cartilage from behind along the wanted anthelix. In 1947 Pierce et al. suggested 8-10 parallel incisions from behind, almost through the cartilage. Stenström (1963, 1966) described an important observation, viz. that cartilage spontaneously bends in the opposite direction of a scratched surface. The author utilized this observation in his operation for outstanding ears, using a superficial scratching on the anterior aspect of the cartilage to obtain a soft, shapely anthelix. Apart from ear bandage no fixation of the ear was applied. The observation of Stenström is used in the operative procedure described below.

Operative Technique

Sterile cleaning of the external ear and all surroundings is used according to the normal surgical principles. When the ear is pushed back against the head, the normal anatomical details can be seen, so that a marking with dye can be made where the new anthelix and crus anthelicis inferior is desired (Fig. 2). Patients with protruding ears often reveal, in addition to the missing or slightly developed anthelix, a large conchal cavity with a high conchal wall. Therefore it is often necessary to place the coming anthelix somewhat down in the conchal cavity especially at the most distal part. A skin incision is made on the posterior aspect along the coming anthelix fold. The cartilage is separated to the free helix edge, and great care is taken to free around the cauda helices and antitragus. Bleeding vessels are clamped, but the clamps can be removed again after a short while. Only on rare occasions is it necessary to ligate a bleeding vessel, and so far we have not seen haematomata which had to be treated. Through the fissura antitragohelicalis it is easy to gain access to the anterior aspect

of the cartilage, and subcutaneous undermining is carried out along the marked anthelix and crura folds. The anterior aspect of the auricular cartilage is now scratched with a special scratching instrument (Fig. 3). The scratching must not be too deep but has to be continued until the ear spontaneously folds backwards. The scratched area must be 0.5–0.75 cm wide, deepest in the midline and should be continued as far as possible out into the helix fold, to obtain a soft natural-looking passage. The correct position of the ear is often prevented by a considerable thickness of the crura helix and the most posterior part of the antitragus. Thinning of these two cartilage areas from behind should therefore always be performed. The ear is kept in the desired position by four mattress sutures, the upper one placed in the triangular fossa, the other ones in the conchal cavity (Fig. 4). A 2-0 silk suture is inserted from the front and brought back through the skin and cartilage, in front of the anthelix fold. On the posterior aspect, a loop of the suture catches the cartilage behind the anthelix fold, so that the suture in the loop is placed subcutaneously on the front side of the cartilage. The course of the suture is best illustrated in the diagram shown in Fig. 5. When all the sutures are placed, they are tied over small gauze rolls on the front side of the ear. By means of the mattress sutures it is possible to place the ear in the desired position. The mattress sutures are left untied until the retro-auricular wound is sutured with fine chromo catgut. These sutures in the skin have not given rise to any complications. A wet cotton dressing (physiological saline) is placed in the scapular fold, and finally a compressing bandage is placed on the ear. After 10 days, the bandage and the mattress sutures are removed, and a new compressing bandage is then used for another 10 days. This bandage is removed by the patient himself and the patient uses for another 21 days a light stockinette bandage during the night. Mattress sutures caused no complications and at subsequent check-ups there were no visible signs of the

Fig. 3. The specially designed scratching instrument. One for the right ear and one for the left ear.

Fig. 4 Showing the four mattress sutures in place

sutures. None of the patients received prophylactic antibiotics.

The operation was performed under general anaesthesia in young children, while only local infiltration anaesthesia was employed in older children and adults. However for haemostatic reasons local infiltration of the ear with 1 % Lidocaine with noradrenaline was used in all cases.

Check up Examination

The operative procedure described has been used by the author in the Department of Otolaryngology the University Hospital of Aarhus, Denmark, since 1967. The patients subjected to operation during 1967 and 1968 have been called in for check up. During this period the same surgeon operated 105 ears in 55 patients. Of the operated ears, 84 % were re-examined 26 to 5 months (average 16 months) after the operation. There were 24 girls and 20 boys, whose ages ranged from 5 to 21 years one patient was 31 years old and the average age

was 11 years. In six patients, only one ear was operated on. Of the re-examined patients, 65 % knew of one or more family members who had outstanding ears. In 45 of the 55 patients, a pure-tone audiogram was recorded pre-operatively. Normal hearing was present in 42. A slight conductive low-tone loss was found in three. Two of these patients had fairly large adenoids.

All the patients subjected to operation were very satisfied with the result of the correction and some of the children had improved psychically after having had their ears corrected. The check-up showed that 85 % of the patients now had normally placed and anatomically correct looking ears. One patient in whom both ears had been operated on revealed an outstanding right ear at the check-up again placed as before the operation. In another patient, both ears showed an outfalling tendency of the upper helix edge. The remaining 11 patients were found to have well-placed ears, but the anthelix was more marked or irregular than a normal looking ear. Undoubtedly the cause was a too deep and narrow scratching of the cartilage. In addition, these patients had ears with a hard melastic cartilage. Reconstruction of the crus inferior anthelics was performed only in some of the patients. However it is also of great importance

Fig. 5 Mattress sutures tied over gauze rolls.

Fig. 6 The upper pictures showing the patient before operation and the lower ones after the operation.

to make a scratching of the inferior crus. The scratching here must be deeper and narrower than the scratching of the crus antheleus superior. The cephaloscapal angle was measured before and after the operation in all the patients. Postoperatively the angle was considerably decreased in all cases, except in the aforementioned patient with recurrence. In all cases, the angle was found to be much enlarged before the operation, but only a few revealed postoperative angle of about 30° which is usual for a normally placed ear. The reason for this is undoubtedly that outstanding ears are generally relatively large and often combined with a considerably enlarged conchal cavity (Fig. 1).

It is usually stated that the shape of the external ear becomes permanent at about the age of 5 years, but its growth has not termi-

nated at that time. All investigators agree that surgical procedures on the external ear does not depress normal and continued growth, and they also agree that outstanding ears should be corrected before the patient start school, i. e. at the age of 5-7 years.

QUANTITATIVE ANALYSIS OF LANGUAGE PRODUCTION IN PATIENTS WITH DOWN'S SYNDROME

O. Bentzen and O. Nielsen

From the Stat. Hearing Rehabilitation Centre, University Hospital Aarhus, Denmark

The language in persons with Down's syndrome was analysed by two methods: electro-mechanical counting of the letters and statistical counting of letter and words by a computer. Studies based on these methods were performed on the spoken language of a pair of twins 11 years old, one twin being a boy with Down's syndrome.

A main factor in the rehabilitation of deaf and hard-of-hearing children is the level of language development. In individual training and therapy as well as in the investigation of methods, a measure of language development is greatly needed (Bentzen & Willemoes, 1961).

To meet this need, a method of quantitative analysis of individual language production has been developed. This method—called quick check analysis (QCA)—meets the requirements of being both simple and quickly performed. In the following, data collected by this method have been analysed by means of a computer permitting a more detailed analysis of the language.

QUICK CHECK ANALYSIS

Principle. The written or spoken linguistic production of the person examined is typed on a specially constructed typewriter which, at the same time, tabulates the occurrence of the smallest units in written language, i.e. the letters of the alphabet.

This study was carried out with the support of Den. sk Lyngdørlære & Høreløbsforbund.

Method. A black-and-white line drawing, illustrating a family scene in a garden, is used as a test picture. This picture is shown to the person under test, who is requested to describe the picture, and the description is recorded on a tape recorder. A two-minute period of this recorded description is then transcribed on the special typewriter.

Apparatus. An ordinary typewriter has been altered to provide an electric contact for each key including the space bar and shift key. Striking a key closes its contact and causes an electrical impulse to advance in the corresponding counter.

Analysis. Another method of analysis of speech production using the examined patient's description of a test picture was employed by Stone *et al.* (1961) but their analysis of the descriptions was based on speech intelligibility and voice quality. In our work, the analysis is based solely on the symbolic character of the language sample as revealed by numerical analysis of the number of words produced per minute, the average length of the words, the number of nouns, and the number of consonants produced.

Normal Standards

The linguistic production of 50 normal subjects aged from 4 to 80 years was recorded and analysed to provide a basis of comparison with patients.

QUANTITATIVE ANALYSIS OF LANGUAGE PRODUCTION IN PATIENTS WITH DOWN'S SYNDROME

O Bentzen and O Nielsen

From the Sten Hearing Rehabilitation Centre University Hospital, Aarhus, Denmark

The language in persons with Down's syndrome was analysed by two methods: electro-mechanical counting of the letters and statistical counting of letters and words by a computer. Studies based on these methods were performed on the spoken language of a pair of twins 13 years old, one twin being a boy with Down's syndrome.

A main factor in the rehabilitation of deaf and hard-of-hearing children is the level of language development. In individual training and therapy as well as in the investigation of methods, a measure of language development is greatly needed (Bentzen & Willemoes, 1961).

To meet this need, a method of quantitative analysis of individual language production has been developed. This method—called quick check analysis (QCA)—meets the requirements of being both simple and quickly performed. In the following, data collected by this method have been analysed by means of a computer permitting a more detailed analysis of the language.

QUICK CHECK ANALYSIS

Principle The written or spoken linguistic production of the person examined is typed on a specially constructed typewriter which, at the same time, tabulates the occurrence of the smallest units in written language i.e. the letters of the alphabet.

This study was carried out with the support of Den skundtunge danske Valeriusstiftelse.

Method A black-and-white line drawing, illustrating a family scene in a garden, is used as a test picture. This picture is shown to the person under test, who is requested to describe the picture, and the description is recorded on a tape recorder. A two-minute period of this recorded description is then transcribed on the special typewriter.

Apparatus An ordinary typewriter has been altered to provide an electric contact for each key including the space bar and shift key. Striking a key closes its contact and causes an electrical impulse to advance to the corresponding counter.

Analysis Another method of analysis of speech production using the examined patient's description of a test picture was employed by Stone *et al* (1961) but their analysis of the descriptions was based on speech intelligibility and voice quality. In our work, the analysis is based solely on the symbolic character of the language sample as revealed by numerical analysis of the number of words produced *per minute*, the average length of the words, the number of nouns, and the number of consonants produced.

Normal Standards

The linguistic production of 250 normal subjects aged from 4 to 80 years was recorded and analysed, to provide a basis of comparison with patients.

Table 1 *Analysis of the speech production of three groups of subjects: children, adults and elderly subjects over 65 years of age*

Group	n	Words/ min	Average length	Percentages	
				Nouns	Consonants
Small children	40	43	3.50	30.2	60.6
School children	50	65	3.55	31.1	60.8
University students	50	10	3.91	31.9	61.2
Nurses	50	101	3.89	4.8	60.8
Old people	50	71	3.64	70.8	60.7

Description of Test Picture by Normal Subjects (in Danish)

It was demonstrated as illustrated in Table 1 that language production per unit of time is greatest in adults less in the aged and least in children. The same tendency is seen in the average length of words, whereas the frequency of nouns decreases with increasing age.

This method using electro-mechanical counting of basic letter units in the words of a patient's description of a picture was similarly applied to written language. An example listing differences in several languages is shown in Table 2 in which the results are based on the same text translated into six languages.

The difference between the results in the Danish and the English language should be noted as the analysis of the language of the patients with Down's syndrome is based on the English language.

Table 2. *Numerical analysis of written language based on the number of words, their average length and the percentage of consonants occurring in six translations of the same text*

Language	Number of words	Average word length	Consonant percentage
German	99	5.3	61.0
Danish	75	4.81	61.1
French	790	4.63	78.2
Swedish	311	4.46	62.0
Dutch	333	4.4	57.2
English	322	4.04	55.7

It may be asked whether or not word production, average word length, and the percentage of nouns will be sufficient to characterize the quality of the language in general. To answer this question, the available test material was analysed by another method based on the principles of statistical linguistics, using an electronic computer. A comparison of the results indicated that only very little additional information is derived from the use of the more complicated statistical method.

COMPUTER ANALYSIS

Principle The language sample (either written or spoken) from each person examined is statistically analysed to produce the following information.

a. A measure of the amount of information in the sample.

The information content is measured indirectly through a determination of the uncertainty of the receiver of the language sample's content, the message. This uncertainty consists in a determination of the probability of the occurrence of the following word in the text. As an example, a sample phrase beginning with "Mary had a little" will lead to an extremely high probability (or insignificant uncertainty) that the following word will be "lamb". As a second example, the symbols "Z E B-R" will, with a very great probability value be followed by the symbol "A".

The formal concept of uncertainty which has been used is the *entropy* concept as stated in the fundamental works on information theory by Shannon (1948).

The numerical value of entropy is chosen in such a way that large entropy values correspond to great uncertainty so that an entropy value of zero corresponds to certainty. In the foregoing examples, the entropy values of 'lamb and A' approach zero. Entropy is thus the reciprocal of the probability of occurrence.

Entropy values for a given sample provide a valuable characteristic when used together with the other objective and subjective measures. A low-entropy message will be monotonous, probably with a very limited vocabulary and with the frequent use of clichés of no informative value. A high-entropy message will be very changeable, probably with a voluminous vocabulary. Extremely high values of entropy may indicate messages which are not too easily grasped. On the other hand, high entropy values may indicate a lack of content, as in a nonsense poem, or the remark of the Mad Hatter in Alice in Wonderland: 'Like a tea tray in the sky'. If it is our experience that 'sky' may appear in this connexion, then anything may appear so that our uncertainty and, thus, the entropy value will increase rapidly.

b. A vocabulary which gives the numerical tabulation of the frequencies of occurrence of all words appearing in the message.

Apparatus These analyses were performed with the use of the computer system at the computing centre at Aarhus University. The programmes were worked out at the Institute of Statistics and Data Processing of the Aarhus School of Economics and Modern Languages.

Analysis In a previous study the speech production of a 65-year-old woman and a 12-year-old boy (with an IQ of 170) were compared with an excerpt from the novel 'Niels Lyngne' by the Danish author I. P. Jacobsen. The entropy determination is tabulated in Table 3.

In Table 3 the letter H indicates entropy while the subscript indicates the number of symbols involved in the computation: e.g., the heading H_3 indicates that the entropy values was computed from three consecutive symbols. In each of the three samples, it is seen that the entropy value decreases as the length of the word increases, illustrating the fact that the uncertainty of guessing the following letter and hence the entropy value, becomes less after the first five letters or so are known than if only one or two letters are known. This is also confirmed by the values for I. P. Jacobsen's work being greater at every level tabulated in Table 3. In the case of the speech samples, the description of the test picture given by the very intelligent 12-year-old boy includes three times as many symbols as the description by the 65-year-old woman, whose speech is much less informative (lower entropy).

Computer analysis of speech permits the

Table 3. Entropy values for one written and two spoken language samples from three normal subjects

Sample	Entropy values						Number of symbols in the sample
	H	H_2	H_3	H	H_2	H_3	
I. P. Jacobsen 'Niels Lyngne' Boy, 12 years ICA method	4.01	3.53	3.03	-.61	2.23	1.93	4096
Woman, 65 years ICA method	3.90	3.31	2.73	2.32	1.97	1.70	1847
	3.80	3.09	2.46	-.01	1.68	1.43	641

examination of various parameters, e. g. the frequency with which various words occur. This factor provides information of the information value of the sample as this value increases with the number of different words used. This factor which was introduced by Johnson (1939) to characterize the value of a text is called the type token ratio or TTR. The TTR is the ratio of the number of different words to the total number of words in the sample.

ANALYSIS OF LANGUAGE IN PATIENTS WITH DOWN'S SYNDROME

Speech

The electro-mechanically counted letters of the QCA method were supplemented by computer analysis of texts performed with mongoloids. In the case of spoken language a pair of twins were selected to illustrate the process. The twins are 13 years old; the boy is mongoloid while his sister is normal. Both children have been brought up at home but as the family has travelled widely and lived in various countries throughout the world the children have experienced intense linguistic stimulation. Owing to this experience combined with an otherwise stimulating family atmosphere on the whole the 13 year-old boy with Down's syndrome is significantly different from typical mongoloid subjects of the same age who have been institutionalized from early childhood.

Table 4 *Description of the test picture given by a 13 year-old boy with Down's syndrome and by his normal twin sister analysed by electro-mechanical counting of letters*

Subject	Quick check analysis		
	Words/min	Average Word length	Nouns (per cent)
Girl normal	145	3.91	24.5
Boy mongoloid	74	3.75	30.0

Table 5 *Computer analysis of the test-picture descriptions given by the 13 year-old boy with Down's syndrome and by his normal twin sister*

Subject	Entropy values		
	H ₁	H ₂	H ₃
Girl normal	4.0	3.36	2.73
Boy mongoloid	3.97	3.45	2.58

The normal twin sister was taken as the norm for comparison in both methods of analysis. This was necessary because no language analyses for English-language home-raised mongoloids was available. To a certain extent, the normal twin sister's linguistic development must express the approximate level her brother would have reached if he had not been a mongoloid.

Both children were tested with the QCA picture at the same time. The results are shown in Table 4.

The figures listed in Table 4 indicate that the boy with Down's syndrome produced speech with a greater occurrence of nouns, and with words having fewer letters, than his normal twin sister. Both relations suggest a less developed linguistic ability in the mongoloid.

The entropy values for the normal girl and the boy with Down's syndrome (Table 5) do not differ sufficiently to permit their linguistic abilities to be differentiated by the use of entropy analysis.

Comparison of the figures listed in Tables 4 and 5 indicate that computer analysis does not provide more information than was disclosed by the QCA analysis, which seemed to show that the mongoloid boy used a more primitive language than his normal twin sister.

Computer Analysis of the vocabularies

The vocabularies of the two children tabulated under the computer analysis may provide the

Table II Results of computer analysis of the total vocabularies used by the two children during the test period. The nouns which were not used by both of them are listed

Normal Girl			Boy with Down's syndrome
Basket	Hair	Song	Cigar-holder
Bow	Mother	Spot	Flowers
Children	Overall	Table	Lot
Clock	Paintbrush	Tulips	Man
Door	Picture	Vase	Jersey
Father	Pot	Weather	Shorts
Fence	Pull-over		Shirt
Fun			Woman
Special nouns: 22			Special nouns: 9
Nouns in common: 28			

basis of a semantic analysis of the test texts, but this is beyond the aims of the QCA analysis.

The nouns used exclusively by each of the two children in describing the test picture are tabulated in Table 6. It may be seen that the normal girl used differentiated words such as father, mother and tulips, while her mongoloid brother made use of less differentiated collective terms such as man, woman, and flowers.

Conclusions

On the basis of experience with the use of quick check analysis in 250 normal persons of all ages, it was possible to use the quantitative speech analysis to characterize the speech of the boy with Down's syndrome as being the most primitive: he used relatively more nouns and words of shorter average length than did his normal twin sister. This analysis could be carried out without previous knowledge of the examined twins' data.

Computer analysis, which permits a semantic evaluation, confirmed that the above-men-

tioned results are correct. While the normal twin sister used specific terms, her brother with Down's syndrome made use of collective terms, which is an expression of the lower development of his linguistic abilities.

In this example, the measurements of entropy values, which can be done only by means of a computer analysis, did not support the results previously obtained by quick check analysis.

TREATMENT OF DELAYED SPEECH DISORDERS

Sirkka Siirala

From the Department of Otolaryngology University Hospital Helsinki, Finland

The primary requirement in the treatment of delayed speech development is a thorough examination. Frequently it is possible only during the course of treatment to discover the real abilities of these children. Evaluation of this problem demands a large team who together—on the basis of examination—plans a suitable line of therapy for each child. The team determines the best type of school and as far as possible supervises continued therapy. It is essential that the parents' active co-operation is secured, since these children are likely to have difficulties later on at school. If a child can be helped to get on successfully at school in the early stages, it may have a favourable effect on its entire future.

The causes of delayed speech development have been studied since 1961 in the Audiophoniatric Section of the Department of Otolaryngology University of Helsinki. We have also tried to develop the treatment of these children as far as available facilities have allowed.

A team (Böhme, 1966) consisting of a large number of people co-operate in this rehabilitation work: a phoniatrician, an audiologist, a psychologist, two speech therapists, a social nurse, a kindergarten teacher, two auditory rehabilitation assistants, a physiotherapist, ward nurses and children's nurses, as well as a primary school teacher. The phoniatrician and the audiologist examine the patients and refer them to specialists in other branches of medicine. This is necessary because they may suffer from multiple handicaps, often combined with minor brain lesions. In addition to neurological examination and electro-encephalography there is a need for examinations by other specialists, e.g. the otologist, ophthalmologist, child psychiatrist and paediatrician. Of this

team those who are essentially in charge of the rehabilitation are the speech therapists, the psychologist, the kindergarten teacher and the physiotherapist, but the entire hospital staff is also involved in the work.

The psychologist's responsibility is

- I to evaluate the child's abilities by
 - a. standardized test methods, verbal and non-verbal and
 - b. observation of the child both in individual play situations in a special therapy room and in group situations in the ward (Harding, 1965).
- From these tests a picture is obtained of
 - 1 the child's intellectual ability
 - the present level of performance
 - the capacity to develop
 - 2 emotional and social maturity
 - 3 school maturity: a suitable type of school is recommended

II *Psychotherapy* for the children who show definite psychic abnormality resulting from delayed speech development. Psychic disturbances are very common when such an important medium of human communication as speech is defective.

These children are usually either

- 1 timid and withdrawn or
 - 2 restless and aggressive
- III The psychologist's task is also to explain to the parents the child's abilities and possi-

ties (Ereumie, 1964) and try to make them accept their child and take an interest in its rehabilitation. The psychologist should keep in touch with the local child-guidance clinic, with the teachers and with other persons in charge of continued rehabilitation.

The speech therapist is responsible for (Seemas, 1965):

1 The development of the child's language communication

- 1 Establishment of a good contact between the child and the speech therapist.
- 2 Improvement of language ability by means of play therapy
 - a. improving the power of concentration,
 - b. motivation and stimulation of the child to use voice and speech,
 - c. development of "inner language" (thought) and rooting of symbol function (Myklebust, 1957),
 - d. widening of passive vocabulary using at first different objects, toys and games,
 - e. familiarizing the child with the world of sound by means of various sound sources,
 - f. training the child's auditory discrimination and auditory memory
 - g. stimulation and widening of active vocabulary
 - h. training the motor activity of the speech organs.

Initially the instructional materials include only objects, various toys, etc. (Wood, 1964). Later pictures and drawings are added, which are already more abstract. The therapy aims at getting the child to express itself spontaneously which goal is most easily attained by means of play and games (Berry & Elsensohn, 1956).

The rehabilitation of these children is individual, and treatment demands much experience on the part of the speech therapist. She should take the child's entire personality into account and not confine herself to the language problem alone.

II Speech instruction proper

This can only be started when the child has acquired enough language to make self-expression of some kind possible:

- 1 Continual widening of the vocabulary
- 2 Correction of articulation:
 - a. word patterns,
 - b. sounds (vowels, consonants and their combinations)
- 3 Correction of sentence structure, grammatical errors.
- 4 Correction of reading and writing disturbances.
- 5 Exercises in the use of the voice.
- 6 Correction of rhinophonia.

III Guidance of parents

The speech therapist should advise the parents as to how to handle their child and what to do at home to promote language ability.

The role of the kindergarten teacher in rehabilitation

1. Improvement of the child's auditory abilities using various singing games with easy words, rhythmic exercises and development of the child's musical ability (various instruments)

II Visual-motor exercises

handicrafts, jigsaw puzzles, modelling, drawing, painting, etc.

III. Accustoming the child to group activities

Daily exercise of this kind, lasting 3 hours, seems to develop the children considerably. Although all children cannot be made to participate in games, they do at least look at the activities of the others, and may perhaps join in another time.

In the case of children whose movements are awkward and poorly developed, daily rehabilitation includes physiotherapy given by a qualified physiotherapist.

The older children—including the 6-year-olds—attend elementary school lessons daily where

they are taught by a primary school teacher. This brings to light the child's attitude towards schooling.—The older boys also receive training in wood work twice weekly.

In addition to individual therapy teaching in groups can be used if suitable groups can be formed.

The team meets twice weekly to discuss the results. An attempt is made to sum up the child's abilities, qualities and capacity to develop and on this basis, to find a suitable type of school and organize continued therapy either in kindergartens or by speech teachers, etc.

The acquisition of language involves a process of learning which may often require years of therapy (Van Riper 1961 1965). The best results are achieved if the parents participate actively in the rehabilitation. They should accept their child as it is and encourage it to express itself. It should be remembered that these children have difficulties at school. If they are helped with their school work from the start, in parallel with continued rehabilitation, then these difficulties can be overcome. The child should learn to read and write during the first two school years. If they are poorly grounded they will not like attending school, and their achievements there will be poor. This will later affect them in their occupation and in their whole life.

DISCUSSION

I Leegaard Do all these children have hearing defects, or are there other reasons for their retarded speech, i.e. brain or mental defects? If so, is the programme for rehabilitation the same in all groups?

B Fritzell What was the lower age limit for starting therapy? What was the average duration of therapy during which the children were institutionalized in the phoniatric ward?

S Siirala (Reply to Leegaard) Causes of the delayed speech were

	No. of cases	Per cent
I Central disorders of language development	113	33.7
II Speech disorders resulting from hearing loss	101	30.1
III Pathological changes in the speech organs	33	9.9
IV Mental retardation	49	14.6
V Stuttering	10	3.0
VI Psychoneurotic disorders of speaking	29	8.7

The type of brain damage is very complicated in these cases.

(Reply to Fritzell) Most of the patients come for treatment at the age of 6 years. Treatment may also start earlier.

A RESEARCH PROGRAMME ON STUTTERING AND STRESS

B. Edgren, R. Leanderson and L. Levi

From the Department of Otolaryngology and the Departments of Psychiatry and Medicine (Laboratory for Clinical Stress Research), Karolinska Sjukhuset, Stockholm, Sweden

A series of experimental stressor exposures is described, in which groups of stutterers had to expose their speech disturbance in public. The subjects' self-rated emotional reactions are compared with their sympatho-adreno-medullary "stress" reactions, as reflected by urinary excretion of catecholamines. The effect of iteration of the experimental situation and the influence of psychotropic drugs were also studied.

In the autumn of 1965 a programme for research on stuttering was initiated on a co-operative basis between the Laboratory for Clinical Stress Research and the Department of Phoniatrics at Karolinska Sjukhuset, Stockholm. Certain aspects of the planning and the methods in one of the investigations were presented at the Helsinki Congress in 1966 (Leanderson and Levi, 1967). Here we wish to survey and briefly report on the background to the research programme and the studies carried out so far. The latest study was conducted in the middle of June this year.

A review of the literature on stuttering reveals an inconsistent and somewhat obscure picture of the causes and development of the syndrome. This is partly due to the complex nature of the problem, but also to the incompleteness of the data on which the authors base their opinions. Most investigators agree, however, that the attitudes of the social environment are of great significance, at least in the development of the syndrome. Clinical experience also indicates that the stutterer attaches great importance to the listener's reaction to his speech. His self-criticism and strong ambition to speak without

stuttering often cloud his experience of the listener's reaction.

1 Exposure to Televised Stuttering

How then do non-stutterers react to stuttering, and how do stutterers react, when faced with the same situation? To study this question under controlled conditions we prepared television recordings of a standardized interview with severely stuttering patients and then played back these interviews to an audience consisting of the subjects in the experiment. By using such recordings one avoids an interaction between stutterer and audience and thereby keeps the stimulus situation under control. The present audience comprised three groups, each with five subjects, two of the groups being made up of stutterers. One of the latter groups comprised active members of a society of stutterers in Stockholm, who thus had experience of regular contact with stuttering, while the other group lacked such experience. The third group consisted of non-stuttering controls. The showing of the televised interviews took two hours and was preceded and followed by a control period of two hours. Biochemical variables, including urinary excretion of adrenaline, were measured (Euler and Lohajko 1961) and the subjects rated their subjective reactions, such as "unpleasantness" on an 11-point scale.

The adrenaline excretion in the three groups is shown in Fig. 1 with the adrenaline output plotted against the vertical axis. The non-

Fig. 1 Urinary adrenaline excretion in controls (left), stutterers with group experience (middle) and stutterers without group experience (right) during control conditions and during viewing and listening to televised interviews with severely stuttering patients. Broken lines indicate mean values.

stutterers—left figure—showed a small range and a *decreasing* tendency throughout in agreement with the circadian rhythm in adrenaline excretion (Leanderson and Levi 1966). The two groups of stutterers, on the other hand, showed great interindividual differences, with an *increasing* tendency in mean adrenaline excretion during the television period.

Fig. 2 shows the subjects ratings of their experiences in the variable "general emotional arousal". It may be seen that all three groups reacted similarly. The group of non-stutterers, however, included two persons who reported indifference.

Thus, the stutterers exhibited a stronger adrenaline reaction than the non-stutterers, but did not report stronger emotional reactions. This may be due to psychological defence

mechanisms possibly present in the stutterers, e.g. denial.

2 Reactions to Psychotropic Drugs under Basal Conditions

To study the reactions of stutterers to psychotropic drugs, an explorative study was undertaken under controlled basal conditions. Strict instructions were given about sleep, smoking, intake of food and fluid, etc. during the last 24 hours before the evening of the investigation (cf. Levi, 1967). The experiment comprised three two-hour periods—control period, drug period, and post-drug period. Urine samples were collected at the end of each period and emotional experiences were self-rated every half hour. The 49 subjects had been randomly grouped.

GENERAL EMOTIONAL AROUSAL

Fig. 2. Self-rated general emotional arousal during the conditions and in the groups described in Fig. 1 (1 point = no arousal, 11 points = extreme arousal).

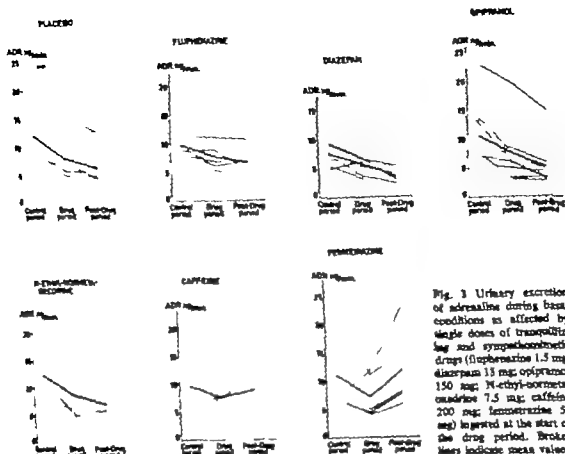

Fig. 3 Urinary excretion of adrenaline during basal conditions as affected by single doses of tranquilizing and sympathomimetic drugs (fluphenazine 1.5 mg; diazepam 15 mg; opipramol 150 mg; N-ethyl-normetazocine 7.5 mg; caffeine 200 mg; fenmetrazine 50 mg) ingested at the start of the drug period. Broken lines indicate mean values.

Fig. 3 shows the adrenaline excretion of the subjects after single doses of three tranquilizers and three sympathomimetics, respectively and a placebo all administered at the start of the "drug period". The reactions in the placebo and tranquilizer groups reflect the decline in adrenaline excretion due to circadian rhythm, whereas the groups given sympathomimetics exhibit an increasing trend during the post-drug period. Self-rated "stress" was low in all groups and during all periods. No significant drug effects could be demonstrated, probably because the subjects were under basal conditions throughout the experiment.

The results during these basal conditions are similar to those one would expect from a normal population. The study also provided information

concerning base-line levels of the stutterers for the experimental situation that was to be used in subsequent studies.

3 Reactions to Public Speaking in Stutterers and Non-stutterers

The next step was to let 14 stutterers expose their speech disturbance in a standardized experimental situation. This now lasted four hours, a control period of two hours being followed by a (two-hour) speech period. During the speech period, the subjects were asked several times and in random order to read a text and to describe pictures projected onto a screen. On a later occasion, 15 non-stutterers (former hoarseness patients) were exposed to the same situation, serving as controls.

Fig. 4 Urinary excretion of adrenaline before and during a stressful situation (public speaking) in stutterers (left) and in non-stuttering controls (right). Broken lines indicate mean levels.

Figure 4 shows the adrenaline excretion in stutterers and non-stutterers in the control and the speech periods. It may be seen that the increase amounted to 150 per cent for the stutterers but only to 40 per cent for the controls. This strong reaction in the stutterers—some values were among the highest ever recorded in the stress laboratory—are reflected by the self ratings (Fig. 5). The curves show that the stutterers reported an increase in unpleasant feelings during the speech period and

Fig. 5 Mean self-ratings of "unpleasantness" in stutterers and non-stutterers during the conditions described in Fig. 4 (1 point scale).

Fig. 6 Mean self-rated eagerness during the conditions described in Fig. 4.

that the non-stutterers did not. However it may be noted that although many of the stutterers were observed as being clearly embarrassed and greatly inconvenienced, the emotional reactions reported by the stutterers were of a moderate intensity.

As regards self ratings of experienced eagerness" (Fig. 6) the reaction was fairly similar in the two groups though the stutterers reported

Fig. 7 Urinary adrenaline excretion in a group of stutterers before and during public speaking following drug treatment for 27 days (first session, left) and 54 days (second session, right). Broken lines indicate mean values.

STUTTERING TENDENCY

Fig. 8 Pooled mean self-ratings of "stuttering tendency" before and during public speaking in 20 stutterers after short-term treatment with placebo and diazepam (11-point scale).

somewhat higher values. A possible, tentative speculation concerning the relationships between the physiological and psychological reactions is that a positive experience, such as "eagerness" would be paralleled by a moderate increase of adrenaline excretion, whereas a negative experience, such as "unpleasantness" could be paralleled by a more marked increase.

4 Drug and Habituation Effect on Stress Responses during public Speaking

The study of reactions in stutterers to public speaking was also designed to include effects of long-term medication and of "habituation". Opipramol (50 mg \times 3), diazepam (5 mg \times 3) and placebo were administered in a double blind cross-over design during two consecutive periods of 27 days each. The stutterers were exposed to the public speech situation twice, namely at the end of each period of medication. The catecholamine excretion levels as well as the psychological self-ratings exhibited marked "habituation" effects, i.e. the reactions were less pronounced during the second exposure.

Thus, it will be seen from Fig. 7 that in several subjects the adrenaline excretion this time actually decreased from the control to the speech period. This was reflected in a corresponding decrease in the emotional reactions reported by the subjects.

As concerns drug effects, we found that

opipramol did not modify the stressor induced adrenaline increases during any of the exposures. On the other hand, 54 days of diazepam treatment were accompanied by a turn of the stressor-induced adrenaline increase into a decrease. Although this group comprised only two subjects—three of the original five dropped out during the course of treatment—these data justified a further study on the effects of long-term diazepam treatment.

5 Effects of Short and Long-Term Treatment with Diazepam

Two separate diazepam trials have been made, one with a single day of treatment (5 mg \times 3), to study the effects of short-term medication, and one with this dose for 54 days. The subjects of these two trials were taken from the waiting-list for stuttering therapy.

In the one-day treatment trial, using the double-blind cross-over design, diazepam ($n = 14$) and placebo ($n = 15$) were administered on two days at an interval of one week. The data are still being processed, but preliminary results indicate a drug effect in the following respects.

The self-ratings of "stuttering tendency" while the subjects were on diazepam and placebo, respectively are shown in Fig. 8 (pooled ratings from both occasions, $n = 20$). It will be seen that throughout both periods the stuttering tendency was rated lower if the subjects were on diazepam.

Figure 9 shows the self-ratings of "stress"

Fig. 9 Pooled mean self-ratings of emotional stress in the subjects during the conditions indicated in Fig. 2.

Fig. 10. Urinary adrenaline excretion after one day of placebo treatment (left) and diazepam treatment (right). Experiment 1 was conducted one week after Experiment 1. Broken lines indicate mean levels.

during the same trial. A similar drug effect was noted here.

It may be seen from Fig. 10 that the adrenaline excretion levels during the first session were lower in the diazepam group.

In the 54-day treatment trial, the adrenaline excretion of the diazepam ($n = 11$) and placebo ($n = 5$) groups is shown in Fig. 11. The mean increase in the placebo group was about 200 per cent. In the diazepam group the rise was

more moderate. In several subjects the excretion remained on a low level throughout the session.

Other data from this study—derived from the diaries kept by the subjects, ratings during the experimental sessions, personality inventories, and the patients' histories as regards stuttering—have still to be analysed. Further reports on these studies will be published.

THE SITUATION OF THE LARYNGECTOMIZED PATIENT

P. Kitzling and N. G. Toremaalm

From the University Department of Otolaryngology Almqvist sjukhuset Mölndal Sweden

The patients' psychological and social problems in connection with laryngectomy have been studied by an extensive pre- and postoperative inquiry. Smoking habits seemed to decrease postoperatively whereas no influence or a slight increase in the consumption of alcohol was registered. Some patients experienced depression, more often as a reaction to the impairment of speech rather than to the diagnosis of cancer. Most of the patients under 65 have learned to communicate by occlusal speech and are also working full-time in their original occupations. The importance of careful pre-operative penetration of surgical, mental and socio-medical problems as well as occlusal speech demonstrations is emphasized. This is best achieved by intensive information given to the patient, his relatives and his employer by means consisting of the surgeon, the phoniatrist, the logoped and the social worker.

The incidence of laryngeal cancer has increased in Sweden as well as in many other countries during the last decade. The reason is not known. Smoking has been supposed to be an important aetiological factor and the increasing industrial outlet of dusts and fumes has also been suspected. In the opinion of most authors, stage I of laryngeal cancer can be successfully treated by radiotherapy. Stages II and III also seem to have a fairly good prognosis, provided prompt and adequate surgery is performed. In spite of this, however, it is clear that great social problems will appear for the individual patient after the operation. The loss of normal voice constitutes indeed a great handicap, but not to such an extent that necessary and well planned surgical intervention needs to be postponed in favour of radiotherapy alone. The aim of this report is to present a pilot study regarding medical, social and

psychological problems in connection with laryngectomy in order to obtain information of the patients' reactions and the degree of handicap after this type of operation.

METHOD AND MATERIAL

The patients were checked from three points of view from the moment of diagnosis through the pre- and postoperative stages and also during a rehabilitation period of varying length. The follow-up programme included repeated personal interviews, which were completed by an extensive questionnaire containing 100 questions. This had been prepared in collaboration with sociologists and psychologists.

This preliminary report includes only 27 cases. A more extensive survey including a brief review of the relevant literature is in preparation (Kitzling & Toremaalm, 1970). Only problems regarding speech rehabilitation, occupational rehabilitation, smoking habits, alcohol consumption and some psychological reactions after the operation will therefore be summarized here.

The number of patients, who were all men, and their ages at operation are shown in Fig. 1. Seventeen patients were under 62 years, while 10 were over 65. Eight patients had from the beginning been judged appropriate for radiotherapy in spite of a growth which was classified as at least stage II. They were, however, later subjected to operation owing to recurrence of their cancer or insufficiency of pre-

Fig. 1. Distribution of the patients according to age and pre-operative treatment

liminary treatment Neck dissection was indicated only in three cases without obvious influence on their ability to practise oesophageal speech

RESULTS AND DISCUSSION

It is always difficult to make an objective estimation of the effectiveness of oesophageal speech ability. We have in our study practised a type of double control. The patients subjectively estimated their own capacity to speak comfortably and to make themselves understood in different social situations. This con-

trol was supplemented by repeated tape recordings and by the logoped's opinion. In this way a satisfactory evaluation was possible. The results are shown in Fig. 2. It is clear that the age of the patient is of great importance in speech rehabilitation. Among eight patients over 67 only one attained good verbal ability. Below 65 however speech rehabilitation was nearly 100 per cent. Only two men in this group failed to learn to speak. One of them had been treated for schizophrenia for many years and the second was an uncommunicative independent workman. Three patients, all

Fig. 2. The patients' ability or failure to learn oesophageal speech

ker long but fruitless training, had to be equipped with an "artificial larynx" (vibrator). Thus, a total of 18 patients became good oesophageal speakers (67 per cent). This agrees with previous reports on series of unselected patients from Europe and the U.S.A. (Horn, 1962; Seemon, 1958).

Many questions were designed in order to observe psychological reactions to the operation. The investigation confirms an earlier supposition, viz. that patients with cancer of the larynx very often are compulsive smokers and heavy drinkers (Nahm & Golden, 1963). It is, however, not possible to decide if these statements have had an aetiological influence because these questions are of a very complex nature. Another aetiological factor which does not seem to be given sufficient attention in the literature, is the effect of chemical air pollution. As many as 19 of our patients had been exposed to air contamination during long periods, either in their present or a previous occupation. Above all, metal dusts and chemical fumes were reported.

The patients' smoking habits are illustrated in Fig. 3. Before the operation, there were two non-smokers and 19 heavy smokers with a consumption exceeding 20 cigarettes a day. The patients had, on the average, started to smoke when they were between 14 and 17 years of age. Postoperatively most patients stopped smoking and none smoked heavily. Five patients are still moderate smokers. Instead of smoking through the tracheal stoma, they have learnt to practise a special mouth-puffing technique which may not be dangerous with regard to a concomitant bronchial cancer.

Contrary to smoking habits, alcohol consumption does not seem to be influenced statistically by the operation (Fig. 4), but it must be borne in mind that subjective information as to drinking habits must always be looked upon with scepticism. Our findings based on frequent postoperative consultations and our good contact with the patients' relatives suggest that a moderate increase in alcohol consumption occurs postoperatively. This is also in ac-

Fig. 3 Pre- and postoperative smoking habits.

cordance with previous French and American reports (Vallery & Cornut, 1962; Webb & Irving, 1964). The increased alcohol consumption may be a symptom of some depressive neurosis, which can prevent effective speech training and thus delay the patient's rehabilitation.

Only 10 of our 27 patients had gone through the operation without any signs of depressive reactions. Among those who suffered from such symptoms, only five could be classed as severe cases, but none of them had contemplated suicide. Depression was most pronounced in the period between diagnosis and operation. It seems therefore valuable to keep the patients with laryngeal cancer under close observation and give them adequate and frequent information during this period. We have prac-

Fig 5 Age distribution working capacity and occupational rehabilitation

tised group information given by the surgeon, the phoniatrist, the logoped, the social worker and, last but not least confronted the patient with a well rehabilitated and good oesophageal speaker.

Many authors report a period of depression in direct connexion with the operation due to the enforced postoperative aphonia. Such reactions were seen in only two of our patients. We believe that this shows that the pre-operative information was not only sufficient but also exerted a positive influence on the course of healing. The greatest psychological problem was obviously the loss of the normal voice. This was stated by 13 patients before the operation and none of them had changed opinion 6 months later. The fear of cancer *per se* was initially indicated as the most serious problem by 12 patients. This figure was, however reduced to none immediately after the operation and to only seven 6 months later. Thus, the fear of cancer decreases as a result of a post-operative course without complications.

Only five patients were worried about their occupational situation and the family economy after the operation. The best help to overcome these problems was provided by close relatives in 15 patients and by the above mentioned team of informers in 13. Seventeen patients reported postoperatively the same good men-

tal condition as they had had before the operation whereas seven had become more restless and nervous.

It is a well known fact that some deaf persons often have a tendency to be aggressive due to difficulties in establishing personal contacts. We found the same reaction in three cases after laryngectomy followed by insufficient speech rehabilitation, and presume an analogous explanation for this. Fortunately enough, 22 patients expressed the opinion that relatives, friends, and also strangers, are appreciative of their strange handicap. The same patients also stated that the thorough information, the listening to a good oesophageal voice and our preliminary contact with the respective employers had been the most positive steps to prevent depressive reactions.

Finally some information as to occupational rehabilitation will be of interest. Most patients under 65 years returned to their former work, and only a few changed occupations (Fig. 5). The only exceptions were again the schizophrenic mental patient and a chronic alcoholic addict.

Although the present case material is small, it has given us a good insight into the patients' reaction patterns. The extensive questionnaire and the repeated interviews may be considered overambitious as a routine but we are of the

Fig 1

RESULTS AND COMMENTS

Measurements were performed on 20 patients, most of them were studied before and at certain intervals repeatedly after laryngectomy. In most cases, healing occurred without complications, and none of the patients complained of dysphagia, although pre-operative radiotherapy had been given to several of them. In one patient who had received pre-operative radiotherapy for a supraglottic cancer a hypopharyngeal fistula developed. However this healed rapidly after which the patient acquired a good oesophageal voice.

The recordings from three typical cases are presented here.

Fig. 1 shows deglutition pressures from a 59-year-old man given pre-operative radiotherapy before laryngectomy. The pressure recordings were made simultaneously from a segment of a length of 10 cm from the pharynx to the sphincter. The arrows mark the onset of deglu-

titation after administration of a sip of water. Before operation (A) the elevated resting pressure in the sphincter is decreased and the pressure in the pharynx is increased by swallowing, as is normally found. During swallowing, the pressure in the sphincter rapidly increases and returns to normal resting tonus. The increased pressure passes into the oesophagus, in which a wave of peristalsis starts. The recordings show normal pre-operative function of the pharynx, hypopharynx and oesophageal sphincter. Postoperatively (B) the elevated resting pressure in the sphincter is not detectable, and swallowing a sip of water (arrow) causes no decreased pressure in the sphincter. The pressures in the pharynx and sphincter increase simultaneously and rather weakly. After the first few contractions, another weak wave of contraction initiates without complete relaxation, indicating a tendency to slight spasm in the scarred region of the hypopharynx. Similar pathological pressure recordings were found in all but one of the patients after laryngectomy. Only one patient complained of dysphagia. He was 80 years old and revealed a heavy spasm in the sphincter postoperatively and did not acquire an oesophageal voice.

Fig. 2 shows the curves from a 49-year-old man with recurrent laryngeal cancer which had been treated by radiotherapy 4 years before. The patient was hoarse, but he had no dysphagia. The curves in A were recorded before laryngectomy when the patient belched voluntarily. During an oesophageal ructus, the upper part of oesophagus is relaxed by voluntary muscles, which brings about a negative pressure. The two arrows indicate the aspiration of air during inspiration. The recordings were made from a 10 cm segment of the body of the oesophagus and show that the negative pressure phase is followed by the ructus. An increased pressure is recorded in the oesophagus, and the air is momentarily pressed upwards without any antiperistalsis. Swallowing of a sip of water (arrow) results in a normal wave of peristalsis. The curves in B show the condition 1 month after laryngectomy when

MOTILITY OF THE PHARYNX AND OESOPHAGUS AFTER LARYNGECTOMY

N Sandberg

*From the Department of Otolaryngology University of Göteborg Sahlgrenska Hospital
Göteborg Sweden*

Intraluminal pressure recordings were made from the pharynx and the oesophagus in patients with laryngeal cancer. Before the laryngectomy no pathological recordings were found. After the operation none of the patients complained of dysphagia, but most of them showed well-defined alterations in the intraluminal pressures. After swallowing, relaxation and contraction pressures and resting tonus in the pharyngo-oesophageal sphincter were weaker. Peristalsis in oesophagus was usually good. The importance of early training of the oesophageal voice is stressed. Early function of the hypopharyngeal wound area seems to be important.

Laryngectomy disturbs the co-ordination of deglutition, respiration and voice normally performed by the larynx. The vocal powers are lost and a permanent tracheostomy is made. Despite derangement of "the nutritional way" caused by laryngectomy the function of the pharynx and oesophagus after laryngectomy seems to be surprisingly good, and dysphagia is no common symptom after the early postoperative phase. Usually the patients are soon able to take adequate amounts of food. The important practising of the oesophageal voice can also be started early which seems to be of importance in order to obtain a good result.

Normal and abnormal deglutition with special reference to partial laryngectomy was studied by Ogura and his coworkers (Ogura *et al* 1964, Ogura & Mallen, 1965, Staple & Ogura, 1966). The aim of the present investigation was to study the motor function of the pharynx, hypopharynx and oesophagus after laryngectomy by measurements of intraluminal

pressures, since very little is known of what happens to the act of swallowing after the operation. The patients were examined before and after laryngectomy by electro-manometrical recordings from the pharynx, from the pharyngo-oesophageal sphincter and from the body of the oesophagus. The muscles which are of principal interest in the region for the study are the inferior constrictor and the cricopharyngeal muscles innervated by a branch of the vagus through the pharyngeal plexus (Lund & Ardran 1964).

METHODS

The motor activity was examined by measurements of intraluminal pressures in the pharynx and oesophagus and in their junction, mainly according to the principles of Code *et al* (1958). A system of water filled open-tip polyethylene tubes were introduced through the nose and adjusted to the desired positions. The nasal ends of the tubes were connected to electro-manometers, and pressures were recorded on a direct writing 8-channel ECG apparatus (Mingograf Elekta-Schöander AB Stockholm, Sweden) from three different levels simultaneously. The three tips were positioned at a distance of 1 or 5 cm from each other thus allowing recordings from segments of 2 or 10 cm. The resting pressures, the deglutition pressures after swallowing a sip of water and the oesophageal ructus pressures were recorded.

Fig 1

In most cases, healing occurred without complications, and none of the patients complained of dysphagia, although pre-operative radiotherapy had been given to several of them. In one patient who had received pre-operative radiotherapy for a supraglottic cancer a hypopharyngeal fistula developed. However this healed rapidly after which the patient acquired a good oesophageal voice.

The recordings from three typical cases are presented here.

Fig 1 shows deglutition pressures from a 59-year-old man given pre-operative radiotherapy before laryngectomy. The pressure recordings were made simultaneously from a segment of a length of 2 cm from the pharynx to the sphincter. The arrows mark the onset of deglu-

tation after administration of a sip of water. Before operation (A) the elevated resting pressure in the sphincter is decreased and the pressure in the pharynx is increased by swallowing, as is normally found. During swallowing, the pressure in the sphincter rapidly increases and returns to normal resting tonus. The increased pressure passes into the oesophagus, in which a wave of peristalsis starts. The recordings show normal pre-operative function of the pharynx, hypopharynx and oesophageal sphincter. Postoperatively (B) the elevated resting pressure in the sphincter is not detectable and swallowing a sip of water (arrow) causes no decreased pressure in the sphincter. The pressures in the pharynx and sphincter increase simultaneously and rather weakly. After the first few contractions, another weak wave of contraction initiates without complete relaxation, indicating a tendency to slight spasm in the scarred region of the hypopharynx. Similar pathological pressure recordings were found in all but one of the patients after laryngectomy. Only one patient complained of dysphagia. He was 80 years old and revealed a heavy spasm in the sphincter postoperatively and did not acquire an oesophageal voice.

Fig. 2 shows the curves from a 49-year-old man with recurrent laryngeal cancer which had been treated by radiotherapy 2 years before. The patient was hoarse, but he had no dysphagia. The curves in A were recorded before laryngectomy when the patient belched voluntarily. During an oesophageal ructus, the upper part of oesophagus is relaxed by voluntary muscles, which brings about a negative pressure. The two arrows indicate the aspiration of air during inspiration. The recordings were made from a 10 cm segment of the body of the oesophagus and show that the negative pressure phase is followed by the ructus. An increased pressure is recorded in the oesophagus, and the air is momentarily pressed upwards without any antiperistalsis. Swallowing of a sip of water (arrow) results in a normal wave of peristalsis. The curves in B show the condition 1 month after laryngectomy when

Fig. 2.

the patient had a good oesophageal voice. Dry swallowing (arrow) results in a moderate contraction. No resting tonus or relaxation phase is seen. The contraction of the sphincter is followed by a wave of contraction in the oesophagus. Cineradiography showed moderate dilatation of the hypopharynx (Malmquist & Sandberg unpublished).

Fig. 3 shows the deglutition curves from a 50-year-old man with very good oesophageal voice 5 years after laryngectomy and unilateral neck dissection. He had no dysphagia. During deglutition (indicated by arrow) a normal wave of contraction is recorded from the pharynx and hypopharynx. In the sphincter no resting tonus is seen only a tendency to relaxation followed by a weak contraction. When the pa-

tient says "Ja" with his oesophageal voice (two arrows) a moderately increased pressure in the hypopharynx and sphincter is seen. This contraction is followed by another showing pressure waves of the types seen during deglutition which is usually initiated after oesophageal ructus. The patient in Fig. 2 used the "aspiration method" to get an oesophageal voice the patient in Fig. 3 used the compression method.

In most cases a good peristalsis was recorded from the oesophagus. After swallowing a sip of water two patients showed only weak segmental simultaneous contractions, i.e. showed signs of hypomotility. This was seen in one very old patient and in one with recurrent laryngeal cancer treated with radiotherapy one

Fig. 3

year before. These two patients did not acquire oesophageal voices, which most of the other patient managed.

DISCUSSION AND CONCLUSIONS

The investigation confirmed the assumption that dysphagia is not common after laryngectomy. Healing without complications occurred in all cases but one (hypopharyngeal fistula). The undisturbed act of swallowing could partly be explained by the elimination of the respiratory air from the pharynx. This simplifies swallowing, and no dysphagia is experienced despite well-defined alterations revealed by recordings of the intraluminal pressures. A moderate weakening of the striated muscles in the pharynx and the upper oesophagus resulting in low resting pressure in the sphincter and low power of relaxation and contraction would seem to be of minor importance. On the other hand it seems to be important that no spasm of the inferior constrictor muscle and cricopharyngeal muscle exists. This disturbs both walking and practising of oesophageal rumen. The 80-year-old man illustrated this. Staple & Ogura (1966) made the same observation after partial laryngectomy in studies with cine radiography.

It might be concluded that, as a rule, the disturbances of the swallowing mechanism recorded after laryngectomy seems to be of minor importance in the patients' nutrition, but

they could explain why some patients cannot acquire an oesophageal voice despite good psychological condition postoperatively. Thanks to healing without complications the patients were able to start training their oesophageal voice early as a rule 10 to 15 days postoperatively. For psychological reasons, it is important to start this training as early as possible, but it may also contribute to a good restitution of swallowing. Early training exposes the wound area to function (tension and strain) at a time when function improves the appropriate differentiation of the newly formed healing tissue. The importance of function for the maturation of the tissue in healing wounds has previously been stressed by Sandberg (1963).

Fig. 2

the patient had a good oesophageal voice. Dry swallowing (arrow) results in a moderate contraction. No resting tonus or relaxation phase is seen. The contraction of the sphincter is followed by a wave of contraction in the oesophagus. Cine-radiography showed moderate dilatation of the hypopharynx (Malmquist & Sandberg, unpublished).

Fig. 3 shows the deglutition curves from a 50-year-old man with very good oesophageal voice 5 years after laryngectomy and unilateral neck dissection. He had no dysphagia. During deglutition (indicated by arrow) a normal wave of contraction is recorded from the pharynx and hypopharynx. In the sphincter no resting tonus is seen, only a tendency to relaxation followed by a weak contraction. When the pa-

tient says "Ja" with his oesophageal voice (two arrows) a moderately increased pressure in the hypopharynx and sphincter is seen. This contraction is followed by another showing pressure waves of the types seen during deglutition which is usually initiated after oesophageal ructus. The patient in Fig. 2 used the "aspiration method" to get an oesophageal voice; the patient in Fig. 3 used the "compression method".

In most cases a good peristalsis was recorded from the oesophagus. After swallowing a sip of water two patients showed only weak segmental simultaneous contractions, i.e. showed signs of hypomotility. This was seen in one very old patient and in one with recurrent laryngeal cancer treated with radiotherapy one

rapy and the patient thus had voice training for half an hour daily for 5 days a week. The numbers of treatments were: one patient had 16, the majority i.e. 13 patients, had 22-31 and one patient 41 including 13 after the end of radiation therapy.

The treatment was started with slackening and relaxation of the recumbent patient followed by breathing exercises in order to teach the patient the subjective control of the air stream necessary for phonation and, after a while, phonation exercises by the method of Svend Smith with certain modifications. This type of voice exercises differs from others in that it makes use of a considerable supply of air among other things, in order to obtain the Bernoulli effect. In this way you get, a cautious but effective massage of the vocal cords. In the exercises the patient phonates primitive unarticulated sounds completely without linguistic connection, and they are delivered in tones at low frequency in sound series of unequal length and with a varying rhythm. The total time of treatment does not allow advanced exercises so the patient is only generally taught to use the vocal cords as well as circumstances permit, and as much as possible the ability of adaptation to changed conditions in the larynx.

Thus, in principle the radiological and phoniatric treatments are terminated at the same time, and most of the patients are then completely or almost aphonic. The number of days of treatment was about 25 which is to be considered low even for the treatment of a simple phosostenia, and it was not influenced by the pre-morbid voice quality of the patient, which naturally differed from person to person. Voice recordings were made after the end of the treatment and at all check-ups. At the first check-up about 4 weeks later most of the patients had had a useful voice for about one week, and at that time the mobility of the irradiated vocal cord as seen in stroboscopic light

indicated absence of infiltrative processes in all patients. The patients also returned for check-ups at 6 months and up to two years later. At these visits, the patients were also informed of the increased vulnerability in the treated tissues. When necessary some drug for the relief of coughing was prescribed.

RESULTS

In one patient out of the 15 the vocal cords atrophied so markedly that the cords could not be adducted closely enough to admit phonation, and about 18 months after the therapy he had to start phonating with the false vocal cords. Three of the other patients had slight oedema of the upper part of the vocal cords, which did not essentially reduce the phonatory mobility of the vocal cords, while the remaining patients had practically normal vocal cords. In this last group was a patient with relatively thick, epiglottic folds and with relatively severe phosostenic symptoms. All patients except the one with ventricular phonation had voice qualities well within normal limits. The great majority of the patients found voice treatment comfortable while it lasted, and declared that it was of good use also later on. According to some patients, their voices were better at the last check-up than before they fell ill. Some patients, including all with oedema, said that their voices had become deeper and darker than they were at first.

CONCLUSIONS

It is not possible to draw far-reaching conclusions from the series considered in this preliminary report, but it supports rather than contradicts the assumption that it is possible to decrease the risk of radiation damage by using phoniatric treatment, which is therefore recommended.

PHONIATRIC TREATMENT COMBINED WITH RADIOTHERAPY OF LARYNGEAL CANCER FOR THE AVOIDANCE OF RADIATION DAMAGE

S Fex and Birgitta Henriksson

From the Department of Otolaryngology University Hospital Lund Sweden

Patients with cancer of the vocal cords, which is treated by radiation therapy usually suffer considerable discomfort including deterioration of the voice during and for a varying period of time after the therapy. In an attempt to keep the vocal cords otherwise healthy by reducing the fairly great risk of vocal abuse and secondary weakness of the cords, phoniatric treatment and radiation therapy are given in parallel. It is suggested that this might be tried as a prophylactic measure against radiation damage to the vocal cords.

Radiation therapy is often given separately to two or more fields in order to spare healthy tissues as much as possible, but nevertheless the skin through which the rays pass becomes red and painful. This reaction is often treated locally with some ointment. Gradually the field is browned and the patients are told that they should avoid exposing the field to strong sunlight.

These precautions are also taken in radiotherapy of laryngeal cancer in order to spare the skin, but obviously it is not possible to protect the healthy tissues on which the radiation is concentrated, i.e. the closest vicinity of the tumour. As is also generally known a large number of these patients sustain radiation injuries either in the form of atrophy of the tissues of the vocal cords or more commonly oedema of the vocal cords and/or in the arythenoid regions. This oedema usually persists for a long time and gradually a varying degree of fibrosis develops. Respiration, however, is only rarely affected to such an extent that subjective discomfort appears but it is phonation which is made difficult or in some

patients, impossible. The injuries mentioned are usually noticed from some weeks up to a year or more after the end of the therapy but also while therapy is given the patient may have appreciable laryngeal trouble: dysphonia passing into aphonia for one or more weeks, pain in swallowing and now and then a painful cough. The subjective discomforts in these patients could perhaps be reduced if the vocal cords were kept completely inactive during the time of radiation and up to about two months after it. If the patient was completely quiet, but as in this situation the patient would not be likely to follow such instructions, we have never tried it. Instead we have found it reasonable to teach the patient to use the vocal cords as carefully as possible.

METHOD

During 1966-1968 15 of the patients who were given radiation therapy against laryngeal cancer in the Department of Radiotherapy in Lund were simultaneously treated in the Phoniatric Clinic. In these patients, the radiation therapy was given by the same method and with the same radiation source. The phoniatric treatment started with examination and registration of the patient, including recording of the voice. At the same time the patient was carefully informed of the difficulties to come and instructed in voice hygiene. Except for the two cases mentioned below voice treatment was given only in parallel with radiation ther-

THE PLACE OF PHONIATRICS IN THE ORGANIZATION OF MEDICAL CARE

G Bjuggren

From the Department of Phoniatrics Sabbatsberg's Hospital Stockholm Sweden

The phoniatric organization must cover the whole range of speech and voice disorders. In Sweden, medical specialists, phoniatricians, must co-operate with logopedes. In addition to ten years of studies in phoniatrics, the phoniatrician has acquired knowledge in otolaryngology (1 year), audiology child and adult psychiatry and clinical neurology (6 months each). Three years of university studies lead to a degree in logopedics. The phoniatric clinic of regional hospitals, thus team co-operates with other specialists and teams at the same hospital, as well as with other logopedes and other medical and social specialists in smaller hospitals. School speech therapy has its own organization.

Phoniatric organization, like any other kind of organization, is built up of vertical and horizontal relations among a number of different elements.

As usual, the patient is the essential element. His legitimate claims must be met to the extent society places means at our disposal. It is up to doctors and other medical authorities to note these claims and find the best means of satisfying them. When planning the organization of a single branch of medical care, scope is restricted by the manner in which medical care in general is organized and planned in the country.

Phoniatric disorders are disturbances of language speech and voice. These vary greatly in aetiology pathogenesis and complexity of symptoms. They must be treated by specialists in both medicine and pedagogy. Medical science is primarily represented by otolaryngology child psychiatry neurosis psychiatry and clinical neurology. In Sweden as in Finland, our field has its own speciality—phoniatrics.

New Swedish regulations for those wishing to acquire competence in phoniatrics have recently been announced. The training requires $1\frac{1}{2}$ year of studies in each of the subjects mentioned, except for otolaryngology which, as is proper takes up 1 year in addition to $1\frac{1}{2}$ year of audiology. Two years of study are required in the main subject, phoniatrics. The pedagogic form of treatment is practised by voice and speech therapists. There are two separate, parallel lines of study in Sweden. One is a 3-year academic programme, whose latter half is placed in a department of medicine, and which ends with a degree in logopedics. The other line is a special teaching line at the Teachers College for Advanced Studies (Lärarhögskolan). It has a 6-7-year period of training with only 1 year dealing with logopedics. This schooling leads to an appointment as a speech pedagogue at a school speech clinic.

Phoniatrics has been a medical speciality in Sweden for several decades. As I have been led to understand, we are indebted to the initiative and far-sightedness of Professor Gunnar Holmgren for this. In Sweden, phoniatric disorders are a problem for organized medical care programmes. These programmes are administered by way of seven regions, each with a regional hospital in which all medical specialities are represented. Each regional hospital has a phoniatric clinic headed by a phoniatrician with logopedes as speech therapists.

In Swedish schools, phoniatric-logopedic activities are carried out in speech clinics. There

THE MOVEMENTS OF THE TONGUE AND THE SOFT PALATE
DURING ARTICULATION AND THE SWALLOWING PROCESS

Siems Siemssen, Arthur Boberg and Nils H. Buch

*From the Department of Otolaryngology Copenhagen County Hospital Glostrup,
the Radiation Therapy Centre and the Department of Plastic Surgery the Finsen Institute
Copenhagen, Denmark*

The film shows a male patient who had an extensive cancer of the left tonsil. After extirpation of the tonsil, partial resection of the cheek, the left part of the mandible and the maxilla, the movements of the tongue and the soft palate were still perfectly normal, and the actual case was—because of the special circumstances—suitable for a demonstration of these movements.

In technicolor and talking pictures the patient demonstrated open and narrow vowels in connection with different consonants. The difference between orals and nasals is shown.

The motor details are demonstrated at normal speed and in slow motion. The reactions of the above-mentioned organs in the act of swallowing are displayed in special recordings.

THE PLACE OF PHONIATRICS IN THE ORGANIZATION OF MEDICAL CARE

G Bjuggren

From the Department of Phoniatrics, Sabbatsberg's Hospital, Stockholm, Sweden

The phoniatric organization must cover the whole range of speech and voice disorders. In Sweden, medical specialists, phoniatrists, must co-operate with logopedes. In addition to two years of studies in phoniatrics, the phoniatrist has acquired knowledge in otolaryngology (1 year), audiology (child and adult psychiatry and clinical neurology (6 months each). Three years of university studies lead to a degree in logopedics. In the phoniatric clinic of regional hospitals, this team co-operates with other specialists and teams at the same hospital, as well as with other logopedes and other medical and social specialists in smaller hospitals. School speech therapy has its own organization.

Phoniatric organization, like any other kind of organization, is built up of vertical and horizontal relations among a number of different elements.

As usual, the patient is the essential element. His legitimate claims must be met to the extent society places means at our disposal. It is up to doctors and other medical authorities to note these claims and find the best means of satisfying them. When planning the organization of a single branch of medical care, scope is restricted by the manner in which medical care in general is organized and planned in the country.

Phoniatric disorders are disturbances of language, speech and voice. These vary greatly in aetiology, pathogenesis and complexity of symptoms. They must be treated by specialists in both medicine and pedagogics. Medical science is primarily represented by otolaryngology, child psychiatry, neuro-psychiatry and clinical neurology. In Sweden as in Finland, our field has its own speciality—phoniatrics.

New Swedish regulations for those wishing to acquire competence in phoniatrics have recently been announced. The training requires $\frac{1}{2}$ year of studies in each of the subjects mentioned, except for otolaryngology which, as is proper, takes up 1 year in addition to $\frac{1}{2}$ year of audiology. THE MOVEMENTS OF THE TONGUE AND THE SOFT PALATE
DURING ARTICULATION AND THE SWALLOWING PROCESS

Siems Siemssen Arthur Boberg and Nils H. Buch

*From the Department of Otolaryngology Copenhagen County Hospital Glostrup
the Radiation Therapy Centre and the Department of Plastic Surgery the Finsen Institute
Copenhagen Denmark*

The film shows a male patient who had an extensive cancer of the left tonsil. After extirpation of the tonsil, partial resection of the cheek, the left part of the mandible and the maxilla, the movements of the tongue and the soft palate were still perfectly normal, and the actual case was—because of the special circumstances—suitable for a demonstration of these movements.

In technicolor and talking pictures the patient demonstrated open and narrow vowels in connection with different consonants. The difference between orals and nasals is shown.

The motor details are demonstrated at normal speed and in slow motion. The reactions of the above-mentioned organs in the act of swallowing are displayed in special recordings.

cal steps must be taken in many instances. However the phoniatrician is competent to administer limited therapy in the aforementioned medical specialties, which is why collaboration with practitioners of these specialties is necessary.

In the case of certain disorders it is no longer a question of therapy in the customary sense, but of habilitation and rehabilitation, mainly in respect to vocational training, but also in order to induce the patient to be able to cope on his own. Ultimately phoniatrists and logopedes must actively organize co-operation with occupational and social therapists of different kinds so that aphasics, for example are able to utilize their resources for communication and contact after the completion of therapy.

With decentralized care, in which the phoniatrician, for obvious and practical reasons, cannot be consulted except in individual cases, as well as in teams for the care of the aforementioned special forms of chronic illness or handicap in which, for the same reasons, the phoniatrician cannot participate directly the tasks of the phoniatrician must be distributed between the logopede and some representative of the medical specialty most appropriate to the case in question. It is obvious that the logopede, who must represent the entire field in such circumstances, must bear a heavy responsibility. It is also obvious that the better the logopede's insights into the pedagogic and medical aspects of the field, the better prepared is he to accept that responsibility.

It is conceivable that many of my colleagues might immediately fear the prospect of charlatanism. My opinion is that the risk of charlatanism is best checked by knowledge. Another aspect of the problem might be that the logopede in this way could make the phoniatrician superfluous. However hitherto my own logopedes have never questioned my continued existence as a phoniatrician.

DISCUSSION

U Sirlala: If phoniatry becomes a "super specialty" in otolaryngology it will be difficult to get young doctors interested in this field of medicine because the long study time. Already now we have difficulties in getting enough physicians in phoniatry. If we were lucky enough to get these "super-specialists" they would mostly be interested in otology because of the better income from it. The other specialty—phoniatry—would suffer from this.

In Finland, rehabilitation of patients is officially accepted as part of the function of a hospital. In the rehabilitation of oto-rhino-laryngological patients the phoniatrician's contribution is very important and useful. A speech therapist should never work alone, only in co-operation with a phoniatrician in order that good results can be achieved.

A Pretzmann-Jensen: Are there physicians in Sweden and Finland who are educated as specialists in phoniatrics without having recognition as specialists in otology?

G Bluggren (Reply to Sirlala and Pretzmann): We may argue in favour of a lot of different subjects and their merits as necessary requirements in the training of future specialists in phoniatrics. Nevertheless, we have to select and give preference to subjects of greatest importance in acquiring competence as a specialist. Otolaryngology is undoubtedly of basic importance to a phoniatrician. I am the only phoniatrician in Sweden with complete otolaryngological training. There is no doubt that I can really benefit in my work as a phoniatrician as the result of my full competence as such a specialist. One year of training in otolaryngology may be a short time. In my opinion, however the two years of training in phoniatrics itself ought to be partly done in close co-operation with the staff of the otolaryngological clinic of the training hospital and, thus, be a good supplement to the required one year of training in otolaryngology and

is only good to say about these activities as such. But organizing a field as small as this as two independent pyramids, as we have seen in the two parallel educational lines mentioned previously in such a small country strikes me as being ill advised. It is only thanks to the co-operativeness of speech therapists and their interest in the medical aspect that there are any cracks at all in the bureaucratically massive walls of the schools. A few years ago I passed on to responsible authorities in the Swedish Board of Education some of my critical views as well as a number of constructive proposals. I can only hope that they are paid some notice.

Phoniatric activities in a medical care region have their centre in the phoniatric clinic. However a region is relatively large and, therefore many patients live at a considerable distance from the clinic. Thus, logopedic therapy which generally requires as many as 20-30 visits, can create considerable disturbances in a patient's regular activities. For other patients, hemiplegics for example the many long and frequent journeys—perhaps delayed by waiting—can give rise to major physical and emotional problems. Providing hospital beds for such cases would be sheer extravagance. One good solution might be for Mohammed to go to the mountain, i.e. to decentralize. Of course this conflicts with the modern principle of placing medical care on an equal footing with industrial production in large units. But I would personally regard this as a dangerous development if it could lead to compromising an individual's demand for human consideration.

Therefore logopedic activities should be decentralized to a certain extent by establishing logopede appointments at a number of smaller hospitals.

Whenever some disturbance of language, speech and/or voice occurs in conjunction with any kind of chronic illness or handicap requiring special care the most practical solution is, as a rule, to transfer phoniatric logopedic treatment to the institution at which the patient is receiving care. This applies, *inter alia*, to children

with defects of the palate, with cerebral palsy or mental retardation. The care of deaf patients or those with impaired hearing is managed by special organizations. Intimate collaboration between these organizations and the phoniatric clinic is, in principle, natural and proper but, in practice, not always so easy to achieve.

Phoniatricians and logopedes in the phoniatric clinic constitute a team in which the phoniatrician is primarily responsible for examinations and diagnoses and the logopede for therapy. A number of other members could, of course, be included in the team: psychologists, pre-school teachers, occupational therapists, etc.

I lectured on the work of phoniatricians and logopedes in, among other places, Copenhagen a number of years ago and in Oslo a little more than a year ago.

The examination made by the phoniatrician is, as in any other medical examination, general as well as focused on special body systems and functions. This is quite self-evident and is reflected in the training of the phoniatrician. This training integrates the various medical disciplines I just mentioned. In every case, the phoniatrician carries out ear, nose and throat examinations: special emphasis is given to the larynx in cases involving the voice. A more or less limited neurological examination is frequently called for. In the case of retarded speech development, the examination could take on the character of a child psychiatry study. The history is essential in all medical examinations, but is of especial significance in most phoniatric disorders. Psychological and social factors will emerge at the history taking. Voice disturbances very often have a psychogenic origin, and it is generally the social handicap which brings the patient to the phoniatrician. In addition, evaluation of the patient's ability to function socially is generally a determining factor in the phoniatrician's therapeutic decisions.

Even if treatment of phoniatric disorders is largely a question of logopedic therapy medi-

SHOULD PHONIATRY BE AN INDEPENDENT SPECIALITY
OR A SUBSPECIALITY?

O. H. Meurman

From the Department of Otolaryngology University Hospital, Turku, Finland

The role and tasks of phoniatry are of topical interest all over Scandinavia. In this paper the tasks of phoniatry and the Finnish demands on the speciality in this discipline are considered from an otological point of view.

In Finland, phoniatry is an independent speciality of medicine. Recognition as a specialist in this discipline requires basically 2-2 1/2 years experience in phoniatric work and 12 months in otorhinolaryngology. In addition, the candidate must have worked for 6-12 months within the fields of child psychiatry, neurology or psychiatry.

The causes of voice and speech disorders may roughly be classified into peripheral, endocrine, central lesions and combined groups, and the treatment involved therefore ranges under different fields of medicine as follows:

Causes	Field of medicine
Peripheral	
Otogenic	Otorhinology
Rhinogenic	-
Laryngeal	-
Oral	Plastic surgery
Dental	Dentistry
Endocrine	Endocrinology
Central	
Mental	Psychiatry
Neurological	Neurology
Combined	

However both from diagnostic and therapeutic points of view many of the peripheral causes are so intimately related to otorhino-

laryngology that it is not possible to dissociate them from that speciality of medicine. Accordingly phoniatric disorders are, in my opinion, inseparably connected with otorhinolaryngology and they must therefore be diagnosed and treated in ear nose and throat clinics.

For this reason, I suggest that phoniatry should rank as a subspeciality based on a complete training in otorhinolaryngology and supplemented with extensive experience in phonetics, respiratory physiology, endocrinology, neurology and psychiatry.

In this way phoniatry would become a branch of medicine providing improved possibilities both in clinical practice and research, and the phoniatrician would be able to give useful advice to the speech therapists and supervise their work.

DISCUSSION

B. Frittsell: I do not think there is really much disagreement except for semantic reasons. However the ability and training to perform operations could not be used as a criterion of independence. If so, neurology and internal medicine would not be considered independent. In the continued discussion, it is necessary to keep two things apart, viz. educational independence as a separate speciality on the one hand, and organizational independence on the other. If we want to, we may compare it with a Department of General Medical Rehabilitation.

a half year in audiology. The clinical relation of phoniatrics to otolaryngology and audiology is of corresponding importance. Nevertheless, phoniatrics must maintain its own specialty content which has integrated parts of otolaryngology as well as of the other fields mentioned. Such a difference is not essential as regards the aspects of organization. On the contrary, even if phoniatrics dares to run the commonly known risk of dependence on a large and powerful neighbour, the existing connections are of real pragmatic value and should be developed even more.

Professor Siirala supposes that an otolaryngologist who intends to continue his studies in order to become a phoniatrician will abstain from his training when discovering that his income from phoniatric practice will be smaller. Undoubtedly this has been and still is, the case in many instances. But according to new principles in agreements concerning ap-

pointment as a medical doctor in Swedish hospitals, the financial difference between the two specialties will be compensated in future. As regards the possibility of logopedes replacing phoniatricians, I have not expressed any decided opinion. I have only called attention to a problem which is similar to another problem in Swedish medical care. This concerns experiments conducted in which highly qualified nurses take over some medical tasks from medical doctors. In my paper I have already mentioned psychologists and occupational therapists as temporary or permanent members of the phoniatric logopedic team. However in Sweden we have very good collaboration with clinics for child psychiatry and other specialties.

In Sweden, neurological and general rehabilitation clinics, respectively and clinics for long term diseases are attached to hospitals.

SHOULD PHONIATRY BE AN INDEPENDENT SPECIALITY OR A SUBSPECIALITY?

O. H. Meunman

From the Department of Otolaryngology University Hospital Turku, Finland

The role and tasks of phoniatry are of topical interest all over Scandinavia. In this paper the tasks of phoniatry and the Finnish demands on the speciality in this discipline are considered from an otological point of view.

In Finland, phoniatry is an independent speciality of medicine. Recognition as a specialist in this discipline requires basically 2-2 1/2 years experience in phoniatric work and 12 months in otorhinolaryngology. In addition, the candidate must have worked for 6-12 months within the fields of child psychiatry, neurology or psychiatry.

The causes of voice and speech disorders may roughly be classified into peripheral, endocrine, central lesions and combined groups, and the treatment involved therefore ranges under different fields of medicine as follows.

DISCUSSION

B. Fritzell. I do not think there is really much disagreement except for semantic reasons. However, the ability and training to perform operations could not be used as a criterion of independence. If so, neurology and internal medicine would not be considered independent. In the continued discussion, it is necessary to keep two things apart, viz. educational independence as a separate speciality on the one hand, and organizational independence on the other. If we want to, we may compare it with a Department of General Medical Rehabilitation.

N Buch: In Denmark the group working with speech therapy in public schools has strongly characterized the developments during the last few years. Communication problems between the speech therapists and doctors have made the work and its practical effect more difficult. While the working field has been widened, the scientific work on speech disorders has not progressed sufficiently and the limited medical engagement here has been important. A greater medical expertise in this field is essential if we like the teachers and psychologists, want to have a greater influence on this problem, the arrangement and the organisation. Young doctors interested in phoniatrics must be given a reasonable position and such conditions that they have an opportunity to show exactly this necessity of a medical effort, both in clinical and scientific work.

Boberg: I have no competence to speak here. As a speech therapist I just want to ask for

help. Until now every patient with speech, voice or language disorders has only been treated by speech therapists. We do not obtain sufficient knowledge during our training. In order to help the patients in the best possible way better knowledge and research are required, and in that field the members of the medical profession can help us.

O Meurman (Reply): In my opinion, the most important work of a phoniatrician is to clear up the aetiology and to establish the diagnosis. The therapy and rehabilitation follow after that. This is a common law in all medicine.

As long as a phoniatrician works in an ear clinic with continuous possibilities of consultations, his basic training in otolaryngology is perhaps not so important. When he starts to work independently outside the ear clinic the situation is entirely different. In diagnostic work it is very important to have a thorough training in otolaryngology.

DEOXYRIBONUCLEIC ACID CONTENT IN BRONCHOGENIC CARCINOMA

O. GREN

From the Departments of Anatomy and Otolaryngology University of Aarhus, Denmark

The DNA content in biopsy material of bronchogenic carcinoma was measured by a microspectrophotometric technique. The average content of DNA was considerably elevated as compared with the normal bronchial epithelial nuclei. The number of polyploid tumour-cell nuclei was 10 times as large as squamous-cell carcinoma and adenocarcinoma as in oat-cell carcinoma.

The formation of the polyploid nuclei and their role in malignancy are discussed.

It is characteristic of tumour-cell nuclei that they have a high content of DNA, and that the values show a wide dispersion. In normal tissues the values are concentrated around a diploid mode, with a few nuclei within the range up to twice the diploid mode, owing to the DNA synthesis prior to mitosis. In tumour tissue, the values extend from a basal modal level, with many cell nuclei in the range up to twice that level, and often an appreciable number of values above the latter (polyploid cells).

Bronchogenic carcinomata are very suitable objects for the study of the DNA content, because the same organ harbours various histologically well-defined types of carcinoma, whose course and degree of malignancy are well known from clinical observations.

In this biopsy material the average DNA content in bronchogenic squamous-cell carcinoma, adenocarcinoma and small-celled anaplastic carcinoma was found to be much higher than that of the normal bronchial epithelium. The average DNA content was slightly lower in the small-celled anaplastic carcinoma than in the two other groups.

The measurements suggested that the distribution patterns of the nuclei of the three types of carcinoma differed, with only a small number of polyploid cells in the small-celled anaplastic carcinoma. It was found that the number of polyploid nuclei in squamous-cell carcinoma and adenocarcinoma was about 10 times as large as in the small-celled anaplastic carcinoma.

The formation of polyploid nuclei may occur after the synthesis of DNA by an inhibition of the splitting of the chromosomes or of their movements. In tissue culture, unfavourable growth conditions may result in the formation of certain substances which inhibit cytokinesis, and therefore give rise to the production of polyploid cell nuclei.

Provided that the vital processes are preserved, the polyploid cells are not as efficient as diploid cells in cell reproduction. In order to divide once, the former must synthesise more material than the latter. This has also been shown experimentally.

When polyploid nuclei are much more frequent in squamous-cell carcinoma and adenocarcinoma, which have a better prognosis than the highly virulent small-celled anaplastic carcinoma, this may mean that the two former tumour types provide less favourable growth conditions, causing inhibition of mitosis while the cells continue to synthesise DNA, resulting in the formation of these large dark nuclei with a high content of DNA.

The considerably greater malignancy of the

Young doctors interested in phoniatrics must be given a reasonable position and such conditions that they have an opportunity to show exactly this necessity of a medical effort, both in clinical and scientific work.

Boberg I have no competence to speak here. As a speech therapist, I just want to ask for

help. Until now every patient with speech, voice or language disorders has only been treated by speech therapists. We do not obtain sufficient knowledge during our training. In order to help the patients in the best possible way better knowledge and research are required, and in that field the members of the medical profession can help us.

O Meurman (Reply) In my opinion, the most important work of a phoniatrician is to clear up the aetiology and to establish the diagnosis. The therapy and rehabilitation follow after that. This is a common law in all medicine.

As long as a phoniatrician works in an ear clinic with continuous possibilities of consultations, his basic training in otolaryngology is perhaps not so important. When he starts to work independently outside the ear clinic, the situation is entirely different. In diagnostic work it is very important to have a thorough training in otolaryngology.

DEOXYRIBONUCLEIC ACID CONTENT IN BRONCHOGENIC CARCINOMA

O Griesen

From the Departments of Anatomy and Otolaryngology University of Aarhus, Denmark

The DNA content in biopsy material of bronchogenic carcinoma was measured by a microspectrophotometric technique. The average content of DNA was considerably elevated as compared with the normal bronchial epithelial nuclei. The number of polyploid tumour-cell nuclei was 10 times as large in squamous-cell carcinoma and adenocarcinoma as in oat-cell carcinoma.

The formation of the polyploid nuclei and their role in malignancy are discussed.

It is characteristic of tumour-cell nuclei that they have a high content of DNA, and that the values show a wide dispersion. In normal tissues the values are concentrated around a diploid mode, with a few nuclei within the range up to twice the diploid mode, owing to the DNA synthesis prior to mitosis. In tumour tissue, the values extend from a basal modal level, with many cell nuclei in the range up to twice that level, and often an appreciable number of values above the latter (polyploid cells).

Bronchogenic carcinomata are very suitable objects for the study of the DNA content, because the same organ harbours various histologically well-defined types of carcinoma, whose course and degree of malignancy are well known from clinical observations.

In this biopsy material the average DNA content in bronchogenic squamous-cell carcinoma, adenocarcinoma and small-celled anaplastic carcinoma was found to be much higher than that of the normal bronchial epithelium. The average DNA content was slightly lower in the small-celled anaplastic carcinoma than in the two other groups.

The measurements suggested that the distribution patterns of the nuclei of the three types of carcinoma differed, with only a small number of polyploid cells in the small-celled anaplastic carcinoma. It was found that the number of polyploid nuclei in squamous-cell carcinoma and adenocarcinoma was about 10 times as large as in the small-celled anaplastic carcinoma.

The formation of polyploid nuclei may occur after the synthesis of DNA by an inhibition of the splitting of the chromosomes or of their movements. In tissue culture, unfavourable growth conditions may result in the formation of certain substances which inhibit cytokinesis, and therefore give rise to the production of polyploid cell nuclei.

Provided that the vital processes are preserved, the polyploid cells are not as efficient as diploid cells in cell reproduction. In order to divide once, the former must synthesise more material than the latter. This has also been shown experimentally.

When polyploid nuclei are much more frequent in squamous-cell carcinoma and adenocarcinoma, which have a better prognosis than the highly virulent small-celled anaplastic carcinoma, this may mean that the two former tumour types provide less favourable growth conditions, causing inhibition of mitosis while the cells continue to synthesise DNA, resulting in the formation of these large dark nuclei with a high content of DNA.

The considerably greater malignancy of the

N Buch In Denmark the group working with speech therapy in public schools has strongly characterized the developments during the last few years. Communication problems between the speech therapists and doctors have made the work and its practical effect more difficult. While the working field has been widened, the scientific work on speech disorders has not progressed sufficiently and the limited medical engagement here has been important. A greater medical expertise in this field is essential if we, like the teachers and psychologists, want to have a greater influence on this problem the arrangement and the organisation. Young doctors interested in phoniatrics must be given a reasonable position and such conditions that they have an opportunity to show exactly this necessity of a medical effort, both in clinical and scientific work.

Boberg I have no competence to speak here. As a speech therapist, I just want to ask for

help. Until now every patient with speech, voice or language disorders has only been treated by speech therapists. We do not obtain sufficient knowledge during our training. In order to help the patients in the best possible way better knowledge and research are required and in that field the members of the medical profession can help us.

O Meurman (Reply) In my opinion, the most important work of a phoniatrician is to clear up the aetiology and to establish the diagnosis. The therapy and rehabilitation follow after that. This is a common law in all medicine.

THE NOISE DOSIMETER FOR MEASURING PERSONAL NOISE EXPOSURE

S. Lagerholm and N. G. Toremalin

From the University Department of Otolaryngology Alimånska Sjukhuset Malmö Sweden

A pilot study of personal noise exposure measurements with the use of noise dosimeters is presented. The value of objective individual recordings regarding the intensity and the exposure time is emphasized. Unexpected daily variations were detected also among employees assigned to work in fixed noise-level environments. Objective measurements of latency and exposure time completed by calculation of the frequency parameter seem more adequate than the previously used objective measurements of intensity and frequency completed by rough estimation of the time parameter.

The dosimeters have also discovered great variations in the individual noise panorama following change from night to day shift or seasonal production fluctuations. Repair and inspection of factory machines involve also great individual increases in noise exposure.

With the dosimeters it was also possible to distinguish between three different groups of employees in the factory with regard to their exposure to noise. So far it seems practical to allow noise exposure above the linear 85 dB level of 0.5 decibel hour per working hour (dBh/h), whereas an amount of noise exceeding 1.0 dBh/h is not tolerable unless adequate noise protectors are used. Further investigations are necessary before definite prescriptions for the practical utilization of the noise dosimeters can be recommended.

Continuous observation as an aid in hearing-loss prevention can briefly be broken up into a general and an individual programme. The general programme includes good noise insulation of factory premises and suitable design of manufacturing machines, which must be checked by repeated conventional measurements of noise intensity and noise frequency. The result of such "point measurements" can then be graphed as a noise-rating curve as

shown in Fig. 1. These two parameters give an account of the noise panorama of the premises at fixed distances from the noise sources. It is not, however possible from these calculations alone to determine the level of unwanted noise at the ears of the employee. There is also a third factor—the exposure time—which it has so far been possible to estimate only approximately.

The individual programme for the observation of people exposed to noise has up to now mainly been based on the above-mentioned measurements of the premises, which have then been matched against sometimes very unreliable exposure-time estimations, and correlated to certain agreed risk criteria. Analyses of this type are finally completed by annual ENT examinations including an individual tone audiogram. Some places have recommended pre-employment temporary-threshold-shift (TTS) determinations (Nixon *et al.* 1965). The value of this type of examination used as a prognostic test has, however been disputed by Opliger *et al.* (1960) and others.

Among the above mentioned measurements, the conventional analyses of intensity and frequency are the most reliable ones, whereas the earlier subjective exposure-time estimations have very often been a matter of controversy. This is, in our opinion, due to the lack of methods for objective recording of the time para-

small-celled anaplastic carcinoma is due to its greater tendency to rapid growth and rapid metastatic spread and to its invasion of the pulmonary vessels.

If the polyploid cells can be taken as a manifestation of unfavourable growth conditions and a lower virulence it must be assumed that only relatively slight inhibition of the growth occurs in the small-celled anaplastic carcino-

ma as compared with squamous-cell carcinoma and adenocarcinoma, which is in good agreement with clinical observations.

THE NOISE DOSIMETER FOR MEASURING PERSONAL NOISE EXPOSURE

S. Lagerholm and N. G. Toremalm

From the University Department of Otolaryngology Almboms Sjukhuset Mölndal Sweden

A pilot study of personal noise exposure measurements with the use of noise dosimeters is presented. The value of objective individual recordings regarding the intensity and the exposure time is emphasized. Un-expected daily variations were detected also among employees assumed to work in fixed noise-level environments. Objective measurements of intensity and exposure time completed by a calculation of the frequency parameter seem more adequate than the previously used objective measurements of intensity and frequency completed by rough estimation of the time parameter.

The dosimeters have also discovered great variations in the individual noise panorama following a change from night to day shift or seasonal production fluctuations. Repair and inspection of factory machines involve also great individual increases in noise exposure.

With the dosimeters it was also possible to distinguish between three different groups of employees in the factory with regard to their exposure to noise. So far it seems practical to allow noise exposure above the linear 85 dB level of 0.5 decibel hour per working hour (dBh/h), whereas an amount of noise exceeding 10 dBh/h is not tolerable unless adequate noise protectors are used. Further investigations are necessary before definite prescriptions for the practical utilization of the noise dosimeter can be recommended.

Continuous observation as an aid in hearing-loss prevention can briefly be broken up into a general and an individual programme. The general programme includes good noise insulation of factory premises and suitable design of manufacturing machines, which must be checked by repeated conventional measurements of noise intensity and noise frequency. The result of such "point measurements" can then be graphed as a noise-rating curve as

shown in Fig. 1. These two parameters give an account of the noise panorama of the premises at fixed distances from the noise sources. It is not, however possible from these calculations alone to determine the level of unwanted noise at the ears of the employee. There is also a third factor—the exposure time—which it has so far been possible to estimate only approximately.

The individual programme for the observation of people exposed to noise has up to now mainly been based on the above-mentioned measurements of the premises, which have then been matched against sometimes very unreliable exposure-time estimations, and correlated to certain agreed risk criteria. Analyses of this type are finally completed by annual ENT examinations including an individual tone audiogram. Some places have recommended pre-employment temporary-threshold-shift (TTS) determinations (Nilson et al., 1965). The value of this type of examination used as a prognostic test has, however been disputed by Optiger et al (1960) and others.

Among the above-mentioned measurements, the conventional analyses of intensity and frequency are the most reliable ones, whereas the earlier subjective exposure-time estimations have very often been a matter of controversy. This is, in our opinion, due to the lack of methods for objective recording of the time para-

meter. This deficiency in the individual noise injury prevention programme led to the development of the previously described noise dosimeter (Lagerholm & Toremalin 1966).

The aim of this investigation is to present a preliminary field survey using the noise dosimeters continuously on a group of employees in a can factory with very high noise levels. The results are then discussed in order to give preliminary recommendations regarding the practical utilization of the apparatus and also to test the significance of the method before using it as a routine in the social and technical noise prevention programmes.

METHODS

The theoretical considerations, as well as the clinical development and laboratory tests of the dosimeters, will be described (Lagerholm & Toremalin to be published). Therefore only a short summary will follow here. The dosimeter consists of a special microphone, a small transistorized linear amplifier, a logarithmic clipper, a rectifier and a chemical integrator in which unwanted noise can be stored in the form of electric energy. All components are contained in one plastic unit, so that the dosimeter can easily be worn in the chest pocket of an overall. The sensitivity of the apparatus can be adjusted to any desired threshold level. In this investigation, a linear 85 dB level was chosen as the zero line which means that noise with an intensity slightly above 85 dB on one or more frequencies is recorded automatically as a function of time. After a period of a day, a week or a month the accumulated noise excess can be read off on a separate meter. The stored quantity of noise has been calculated in a unit which we so far have called the decibel hour (dBh). One dBh per working hour (dBh/h) means that the wearer has worked continuously in surroundings with a noise intensity of about 86 dB at one or more frequency bands for one hour or at an equivalent higher intensity during a shorter period.

RESULTS

The actual can factory produced different types of noise with rather high intensities. Four different noise sources are shown in Fig. 1. The recommended norm for tolerable noise exposure—the N 85 line—is plotted on one of the curves. All noise sources in the factory had their maximum noise levels within the limits of the dosimeter microphone, i.e. 500–8000 cps.

Thirty-four persons were included in the investigation which lasted for five weeks. The employees were occupied in different sections of the factory. One group of workers was stationed near the same machine all day long, whereas a second group contained workers, foremen and engineers with more mobile and varied duties. The individual amounts of noise exposure, together with the mean values and scatter is shown in Fig. 2. It will be seen (to the left in the figure) that 10 persons were exposed to more than 1 dBh per working hour. This is equivalent to a constant exposure to noise exceeding 85 dB. Five were occupied at automatic stamping presses and four worked at printing presses. The tenth man in this group was a body maker operator manufacturing beer cans. The second group (the middle of Fig. 2) was exposed to 0.5–1.0 dBh per working hour. This group was more heterogeneous, containing workers from different sections of the factory. In the third group (to the right in Fig. 2) the noise exposure did not exceed 0.5 dBh per working hour. The people in this group can be classed as low-risk cases and were often foremen or engineers. Owing to their mobile occupations and, as a rule, noiseless surroundings in their ordinary working rooms, the total exposure time was small but varied widely from day to day.

From the total case material in Fig. 2, four individual day-by-day exposure curves are shown in Fig. 3 a–d for closer analyses.

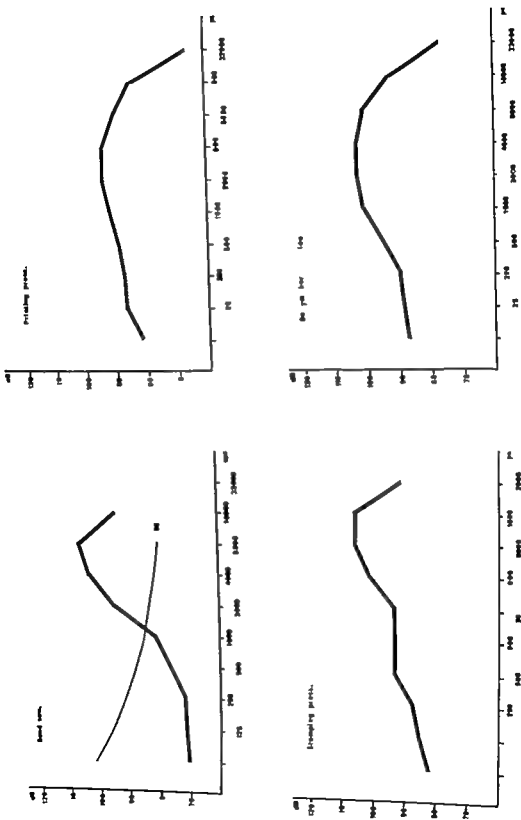

Fig. 1 Noise-rating curves characterizing four different manufacturing machines in can factory

Fig. 1. Individual noise exposure for 34 employees recorded by the noise dosimeter. Mean values and scatter in dBh/h (decibel hour per working hour) during five weeks.

1 A.O. (Fig. 3a) is a 5 year-old employee. He has worked in the can factory since 1935. Throughout this investigation he was occupied at an automatic stamping press with a measured noise level of 90–100 dB (Fig. 1 bottom left). The dosimeter curve shows a mean value of 1.0 dBh/h with a scatter of 0.9–1.8 dBh/h. The total exposure during 15 whole working days was about 160 dBh.

2 K.H. (Fig. 3b) is 34 years old. He has worked in another factory with high noise levels for 10 years before he entered the can factory. Here he has been occupied at a body maker with a noise level of about 100 dB. He had a mean value of 1.7 dBh/h and a scatter of 0.9–1.47 dBh/h. The prominent rise on the 14th and 15th days was due to a change-over from night work to day work.

3 N.N. (Fig. 3c) is 4 years old. He began in the can factory in 1953 and has always operated a printing press with a noise level of about 90 dB. He had a mean value of 1.05 dBh/h and a scatter of 0.76–1.70 dBh/h. The cause of the extreme rise on the 18th day is not exactly known, but may be due to machinery trouble. Occasionally metal sheet becomes jammed in a machine. The distance to the noise source decreases during repair and the noise exposure increases.

4 R.R. (Fig. 3d) is fourth example of individual

noise exposure detected by the noise dosimeter. He is 25 years old and a typographer in his first year at the factory following four years in a printing office. He belongs to the least exposed and had a mean value of 0.87 dBh/h and a scatter of 0.59–1.34 dBh/h. Also in this case however daily fluctuations can be seen, with an unexpected increase during three days.

The recordings were read by one person, who also gave necessary information to the workmen. The noise dosimeters were well tolerated by every individual and no problems appeared regarding the daily functioning and reading of the apparatus.

DISCUSSION

Previously it has been the rule to make *objective measurements of intensity and frequency*, whereas the exposure time has only been briefly estimated. This is effective only if the worker always has a permanent working place. This is, however, not the usual condition in

Fig. 3 a. Automatic stamping press operator (measured intensity 90-100 dBA). A. O. Mean: 1.23 Scatter: 0.92-1.75

Fig. 3 c. Printing press operator (90 dBA). N. N. Mean: 1.05 Scatter: 0.76-1.7

Fig. 3 b. Body-maker operator (100 dBA). K. H. Mean: 1.07 Scatter: 0.9-1.47

Fig. 3 d. Printing press operator (90 dBA). R. H. Mean: 0.82 Scatter: 0.59-1.34

modern industries, which is also seen in the present individual scatter (Fig. 3).

We have therefore preferred to make *objective measurements of intensity and exposure time* and to calculate the frequency parameter as it is not possible to obtain a total frequency analysis by means of a pocket-sized measuring apparatus. This is, in our opinion, not even necessary for the actual purpose, which is to mirror the day-to-day level of individual noise exposure. We have found that most ordinary

industrial equipment and machines contain a maximum intensity hump somewhere in the frequency range 500-8000 cps. This is exemplified in Fig. 1. The finding has been the basis for the choice of an acceptable dosimeter microphone, which must naturally be small, reliable in operation, shockproof and insensitive to temperature (Lagerholm & Toremalm, in press). Thus, the dosimeters work independently of the position of the actual intensity hump within the above-mentioned frequency range.

The four individual examples (Fig. 3) include people who are very often considered to have a fixed working place. This conception

Fig. 2. Individual noise exposure for 34 employees recorded by the noise dosimeter. Mean values and scatter in dBh/h (decibel hour per working hour) during five weeks.

1. A. O. (Fig. 3 a) is a 52 year-old employee. He has worked in the can factory since 1935. Throughout this investigation he was occupied at an automatic stamping press with a measured noise level of 90–100 dB (Fig. 1 bottom left). The dosimeter curve shows a mean value of 1.2 dBh/h with a scatter of 0.9–1.8 dBh/h. The total exposure during 15 whole working days was about 160 dBh.

2. K. H. (Fig. 3 b) is 34 years old. He has worked in another factory with high noise levels for 10 years before he entered the can factory. Here he has been occupied at a body-maker with a noise level of about 100 dB. He had a mean value of 1.7 dBh/h and a scatter of 0.9–1.47 dBh/h. The prominent rise on the 14th and 15th days was due to a change-over from night work to day work.

3. N. N. (Fig. 3 c) is 42 years old. He began in the can factory in 1953 and has always operated a printing press with a noise level of about 90 dB. He had a mean value of 1.05 dBh/h and a scatter of 0.76–1.70 dBh/h. The cause of the extreme rise on the 18th day is not exactly known, but may be due to machinery trouble. Occasionally a metal sheet becomes jammed in a machine. The distance to the noise source decreases during repair and the noise exposure increases.

4. R. H. (Fig. 3 d) is fourth example of individual

noise exposure detected by the noise dosimeter. He is 25 years old and a typographer in his first year at the factory following four years in a printing office. He belongs to the least exposed and had a mean value of 0.87 dBh/h and a scatter of 0.59–1.34 dBh/h. Also in this case, however, daily fluctuations can be seen, with an unexpected increase during three days.

The recordings were read by one person, who also gave necessary information to the workmen. The noise dosimeters were well tolerated by every individual and no problems appeared regarding the daily functioning and reading of the apparatus.

DISCUSSION

Previously it has been the rule to make objective measurements of intensity and frequency whereas the exposure time has only been briefly estimated. This is effective only if the worker always has a permanent working place. This is, however, not the usual condition in

INSTRUMENTATION FOR ACOUSTICALLY EVOKED POTENTIALS USING A PHOTOGRAPHIC AVERAGING TECHNIQUE

E. B. Neergaard and S. Harly

From the Department of Otolaryngology University Hospital, Aarhus, Denmark

The measuring method incorporates photographic device to obtain an average recording of the vertex potentials. The patient is stimulated with pure tones just as in conventional audiometry: the epoch rate is one stimulus per 10 seconds. The vertex potentials are recorded from skin electrodes connected to differential amplifier and displayed on an oscilloscope. The superimposed traces of repetitive responses are transferred to polaroid film via special optical system, and the recording thus obtained reveals the average of the evoked potentials.

The exhibition contains the original instrumentation for optical averaging technique as applied in ERA at Aarhus Kommunehospital. The aim in the instrument construction has been to provide a simple and reliable clinical set-up without the use of expensive electronic computers. A further feature which has been gained in practice is an unusual immunity to noise peaks.

Arithmetic Mean

Median

In physiologic measurements the median will often be preferred to the arithmetic mean.

Optically it may be produced so

Fig. 1 Diagram to explain the formation of mean and median of several traces displayed on an oscilloscope by optical technique

must obviously be revised since many of our subjects with fixed working places demonstrated great individual fluctuations in noise exposure from day to day. It may be said that today there are practically no workers with a constant level of noise exposure. Thus to make use of approximate exposure-time estimations for later correlation to agreed norm tables is a questionable procedure even if it is the only one so far available.

Knowledge of daily variations is of special value during the introduction of new workers to a factory and the installation of new machines. The dosimeter readings are also valuable as indicators of the need for adequate noise protection.

Great variations in the noise panorama appear when workers change from night to day shift, to follow different production schedules. This can be seen in Fig. 3 b. The same effect has also been detected in seasonal production fluctuations. A third factor which may easily be forgotten is the many interruptions in the daily routine. They can be of positive nature (rest breaks) or negative (e.g. repair and inspection of machines). A short increase of 50 per cent is not uncommon as seen from Fig. 3 c.

It is not possible to allow for such factors with the old methods. It would therefore seem to be more satisfactory in the future to follow the noise-exposure variations of every individual continuously. This can easily be done with the dosimeter.

Seen from a prophylactic point of view it is also possible to distinguish between at least three different groups of employees in a factory

with regard to their exposure to noise (Fig. 2). If an individual observation is made for the permanent staff in a factory say monthly it is possible to concentrate different prophylactic measures to the most exposed subjects. This increases the efficiency and reduces the cost of a rational noise-prevention campaign.

It is not possible today to recommend definite criteria for using the dosimeter. The values given in Fig. 2 seem, however, suitable for the present. It will be necessary to study different groups of workers in different types of industry for several years, and to correlate the values obtained by the dosimeter with known point measurements and with employee audiograms. It should then be possible to sum up the total noise-energy load on a single ear and to correlate the figures obtained with audiograms and possible hearing losses. A list of individual noise-exposure figures can also be made and used for different medical and socio-medical purposes. Special investigation programmes have been started in order to gain more experience in this field.

A SURVEY OF NON-TUMOROUS LESIONS OF THE SALIVARY GLANDS

H. Diamant and B. Enfors

From the Departments of Otolaryngology, University Hospital Umeå,
and Söder Hospital Stockholm Sweden

Introduction (Diamant)

The title of this lecture is not fully adequate to the subject. In the first place, the purpose is not to provide complete clinical survey but rather to concentrate on sialadenitis and sialosis. In the second place, some other conditions of non-tumorous nature are touched on only lightly. This paper is the product of close co-operation between Docent Enfors and myself. I shall devote myself to a presentation of the different lesions, while Docent Enfors will report on diagnostic techniques and methods of treatment.

Diseases of the salivary glands are classified as shown in Fig. 1. Fig. 2 gives breakdowns on the basis of sialadenitis and sialosis. These conditions are of interest as regards both diagnosis and treatment. It shall, moreover, discuss secretion disorders, but transecta, strictures, etc. will not be considered, and tumours will be reserved for subsequent lecture.

Classification

1. Disturbance of secretion
2. Tumors
3. Benign strictures
4. Sialolithiasis
5. Sialadenitis
6. Sialosis
7. Tumour

Fig. 1 Lesions of the salivary glands.

Sialadenitis

- a. Acute suppurative parotitis
- b. Chronic recurrent parotitis
- c. Specific infections

Sialosis

- a. Collagen sialosis
- b. Sarcoidosis
- c. Hormonal disturbances
- d. Asymptomatic parotid enlargement

Fig. 2. Sialadenitis and sialosis of the parotid glands.

Examination techniques (Enfors)

The diagnosis in cases of non-tumorous lesions in the salivary glands is generally not difficult. By means of the case history inspection and palpation one can generally arrive at a provisional diagnosis which can be confirmed by further examinations. The inspection should include—and I must emphasize this—inspection of the appearance of the saliva. By massaging the salivary glands and their excretory ducts saliva can be expressed through the orifices. In any case, it is generally easy to massage saliva out of the parotid glands. However from the submandibular glands it is less easy and there one must often stimulate secretion by giving the patient a mouth-wash with a few millilitres of 6 % citric acid solution. Such stimulation is, moreover, always valuable as the amount of secretion response indicates the functional condition of the glands.

The special examinations may be classified in three groups (Fig. 3).

A. Anatomical

1. X-ray Without contrast
Sialography
2. Biopsy Aspiration with the needle
Exclusion of tumour

B. Functional

1. Secretion Sialometry
Chemical analysis
2. Scintigraphy

C. Bacteriological

Fig. 3 Laboratory examinations of the salivary glands.

A dummy patient is used as a source of signals, which through an EEG pre-amplifier are displayed on two separate oscilloscopes. The reason for using two oscilloscopes is to demonstrate two alternative procedures to obtain optical averaging.

One oscilloscope is provided with a very special camera which simultaneously from the same traces on the screen produces three different types of recordings. The top recording is an ordinary photographic picture of the single traces superimposed. Below that is a recording of the traces transformed optically in such a way that the arithmetic mean of the traces

appears. At the bottom similarly there is a recording which gives the median.

The second oscilloscope has an ordinary polaroid camera, and the optical effect necessary for the production of the mean or median relies upon addition of a high frequency auxiliary voltage to the displayed ERA signal.

Both procedures utilize a controlled light dispersion where each point of the trace is transformed into a vertical line segment with a defined light intensity distribution.

At the exhibition it was shown how this is done in practice, and some of the theory was illustrated. Fig. 1 is a reproduction of one of the plates.

A SURVEY OF NON TUMOROUS LESIONS OF THE SALIVARY GLANDS

H. Diamant and H. Enfors

*From the Departments of Otolaryngology University Hospital Umeå,
and Söder Hospital Stockholm Sweden*

Examination techniques (Enfors)

The diagnosis in cases of non-tumorous lesions in the salivary glands is generally not difficult. By means of the case history inspection and palpation one can generally arrive at a provisional diagnosis which can be confirmed by further examinations. The inspection should include—and I must emphasize this—inspection of the appearance of the saliva. By massaging the salivary glands and their excretory ducts saliva can be expressed through the orifices. In any case, it is generally easy to massage saliva out of the parotid glands. However from the submandibular glands it is less easy and there one must often stimulate secretion by giving the patient a mouth-wash with a few millilitres of 0.5% citric acid solution. Such stimulation is, moreover, always valuable as the amount of secretion response indicates the functional condition of the glands.

The special examinations may be classified in three groups (Fig. 3)

A. Anatomical

1. X-ray Without contrast
Sialography
2. Biopsy Aspiration with thin needle
Exclusion of Rusea

B. Functional

1. Secretion Sialogrammetry
Chemical analysis
2. Scintigraphy

C. Bacteriological

Fig. 3. Laboratory examinations of the salivary glands.

A dummy patient is used as a source of signals, which through an EEG pre amplifier are displayed on two separate oscilloscopes. The reason for using two oscilloscopes is to demonstrate two alternative procedures to obtain optical averaging.

One oscilloscope is provided with a very special camera which simultaneously from the single traces on the screen produces three different types of recordings. The top recording is an ordinary photographic picture of the single traces superimposed. Below that a recording of the traces transformed optically in such a way that the arithmetic mean of the traces

appears. At the bottom similarly there is a recording which gives the median.

The second oscilloscope has an ordinary polaroid camera, and the optical effect necessary for the production of the mean or median relies upon addition of a high-frequency auxiliary voltage to the displayed ERA signal.

Both procedures utilize a controlled light dispersion, where each point of the trace is transformed into a vertical line segment with a defined light intensity distribution.

At the exhibition it was shown how this is done in practice, and some of the theory was illustrated. Fig 1 is a reproduction of one of the plates.

Chemical analysis of the saliva as yet plays an unimportant role in clinical work. Our knowledge of the secretion of various substances by dissected glands is too scanty. However it is probable that chemical techniques can be further developed.

It is open to discussion whether salivary-gland scanning should be included with the anatomical or with the functional examinations. Scanning provides information as to the size of the gland, but it is mainly of value as a functional test (Figs. 6 and 7). The radioactive isotope technetium^{99m} which was introduced in the early 1960s, concentrates in the salivary glands, among other organs, a circumstance which permits salivary-gland scanning. One to six millicuries of the isotope are given intravenously. The isotope is secreted with the saliva, and it is therefore necessary to administer atropine before the examination to reduce salivation. Failure to administer atropine is probably the reason for the poor quality of most of the salivary-gland scans reported in the literature. Our experience is not yet very wide nevertheless, the approximately 120 scans carried out at Södersjukhuset (Stockholm) where the technique has been developed together with M. Lind and B. Söderborg, indicate certain relationships between isotope uptake and disease in the salivary glands.

Bacteriological examination of the saliva is of lesser importance.

Diagnosis (Diamant)

Acute purulent parotitis is becoming commoner probably because of the increasing number of operations on patients who are poor risks. This automatically causes an increase in the number of cases of acute parotitis. The patients are often in a very bad condition. In infants, however acute purulent parotitis is less dangerous.

Chronic recurrent parotitis accounts for a very large proportion of our cases and can be diagnosed by using the methods specified by Enfors. This condition is characterized by acute episodes, invariably followed by a

Fig. 6. Salivary gland scanning. Normal picture

more or less pronounced swelling which sometimes disappears during quiescent intervals. The patients do not usually complain of dryness in the mouth because only the parotid glands are affected. Both roentgenological and sialometric changes are found bilaterally even in cases where the patient has pain only on one side. Very often characteristic changes are found even in children. Borchunski, in Poland, has collected a series of over 200 cases of chronic recurrent parotitis in children, diagnosed by means of sialography.

And so we come to the sialosis. I shall not go into controversial questions, such as the dividing lines between sialoadenitis and sialosis, and the terminology proposed by various authors, but shall start right away with the commonest sialosis—namely the collagenous. Very often the lesion of the parotid glands is part of the Sjögren syndrome. These patients complain mainly of xerostomia. Pain is seldom

Fig. 7. Scanning picture showing no uptake in the right submandibular gland. (Chorda tympani previously cut).

Fig. 4 Normal sialography of the parotid gland.

Roentgenographic study is a well tried method. Non-contrast pictures are useful only for detection of salivary stones which are opaque while sialography provides a good picture of the internal morphology of the glands (Fig. 4). The commonest changes are those in the calibre of the excretory ducts and the sialectases. There has been some discussion as to whether sialectases consist of preformed dilatations or whether they occur in connection with the sialography itself. Enerson's study (1968) clearly showed them to be preformed dilatations.

Either aspiration or ordinary biopsies may be taken. In aspiration biopsies the gland is punctured with a fine needle and cell particles

are sucked out. This is a very valuable examination when carried out by an experienced cytologist—indeed in most cases it is as reliable as histopathological examination. It has been alleged that there is some risk of salivary fistulae with excisions for biopsies, but there is no risk if the correct technique is employed. Where a tumour can be suspected, however, the latter method should not be used.

Salivary-gland function is determined mainly by means of sialometry which provides a quantitative record of the secretory capacity of the salivary glands. The saliva from the parotid glands is collected separately from each gland by a suction pump and collection chamber which is placed over the openings of Stenson's ducts. As a result of the secretion pressure the saliva runs out, its volume being recorded by a photo-electric count of the number of drops. The secretion from the submandibular glands must be collected by cannulae inserted into the Wharton ducts. Salivary flow is recorded both when the patient is at rest and when stimulated. Stimulation can be achieved by various methods. Intravenous infusion of acetyl-beta-methylcholine results in a brief but copious secretion of saliva (Fig. 5). Pilocarpine may also be used; it produces a salivary secretion of longer duration. The dosage and rate of infusion must be calculated precisely which can be done by means of an infusion pump. Salivary secretion can also be stimulated by gustatory means—i.e. with a 6% citric acid solution in the mouth.

Fig. 5 The parotid secretion at rest after stimulation with 1 and 6% citric acid and after stimulation with acetyl-beta methylcholine intravenously.

Chemical analyses of the saliva as yet plays an unimportant role in clinical work. Our knowledge of the secretion of various substances by diseased glands is too scanty. However, it is probable that chemical techniques can be further developed.

It is open to discussion whether salivary-gland scanning should be included with the anatomical or with the functional examinations. Scanning provides information as to the size of the gland, but it is mainly of value as a functional test (Figs. 6 and 7). The radioactive isotope technetium^{99m} which was introduced in the early 1960s, concentrates in the salivary glands, among other organs, a circumstance which permits salivary-gland scanning. One to six millicuries of the isotope are given intravenously. The isotope is secreted with the saliva, and it is therefore necessary to administer atropine before the examination to reduce salivation. Failure to administer atropine is probably the reason for the poor quality of most of the salivary-gland scans reported in the literature. Our experience is not yet very wide; nevertheless, the approximately 120 scans carried out at Södersjukhuset (Stockholm) where the technique has been developed together with M. Lind and B. more or less pronounced swelling which sometimes disappears during quiescent intervals. The patients do not usually complain of dryness in the mouth because only the parotid glands are affected. Both roentgenological and sialometric changes are found bilaterally even in cases where the patient has pain only on one side. Very often characteristic changes are found even in children. Burchinzi, in Poland, has collected a series of over 200 cases of chronic recurrent parotitis in children, diagnosed by means of sialography.

And so we come to the sialosis. I shall not go into controversial questions, such as the dividing lines between sialoadenitis and sialosis, and the terminology proposed by various authors, but shall start right away with the commonest sialosis—namely the collagenous. Very often the lesion of the parotid glands is part of the Sjögren syndrome. These patients complain mainly of xerostomia. Pain is seldom

Fig. 7. Scanning picture showing no uptake in the right submandibular gland. (Chorda tympani previously cut).

severe and there is not much enlargement of the salivary glands although this is sometimes the symptom that causes the patient to visit a physician. In many cases, the patient develops no enlargement of the salivary glands and is therefore not referred by the rheumatologists. In Umeå, however, we have had an opportunity to see a number of the cases now under discussion thanks to close co-operation with the rheumatological department and also to the fact that one of our colleagues, Docent Ericson, of the Faculty of Dentistry (Tandläkarhögskolan) has taken a particular interest in the relationship between sialography, sialometry and dryness in the so-called Sjögren syndrome. These cases were diagnosed by means of positive Rheuma-tests in conjunction with marked roentgenological changes in the salivary glands. They have moreover in more than a few cases completely inhibited salivary secretion. Using fine needle biopsy a very highly trained cytologist can distinguish between chronic recurrent parotitis and collagen sialosis. However, the only person who can do this with any degree of accuracy is probably Professor Selfert in Hamburg.

Sarcoidosis, on the other hand, can easily be diagnosed with aspiration biopsy. In this disease, pronounced roentgenological changes are relatively rare. The patients seldom have xerostomia, but they sometimes suffer pain.

Another interesting group is hormonal sialosis.

In this group I include a number of different conditions in which hormone changes may play a role. We examined a series of young girls with enlargement and slight tension in the parotid, but no other symptoms. History reveals changes in the menstruation cycle generally in the form of amenorrhoea. This group also includes patients with enlargement of the salivary glands associated with diabetes, and perhaps also the enlargement that sometimes occurs in older persons.

In the fourth group I include cases in which the patient has enlargement of the parotid gland but in which sialometry, sialography, aspiration biopsy and even routine biopsy are normal. In such cases the salivary gland enlargement follows an asymptomatic course. I am unable to say what the aetiology is.

I should here like to present some material collected over a period of six years. During the first three years there were few cases, but in 1966–1968 the number increased (Fig. 8). It will be seen that rheumatoid sialosis, chronic recurrent parotitis and asymptomatic sialosis are in a clear majority. These data are being analysed from various viewpoints, and we hope eventually to publish them in book form.

Therapy (Enfors)

As regards treatment of non-tumorous salivary gland diseases, the parotitis category presents

many interesting problems. Postoperative parotitis is a serious disease with a high mortality rate. Antibiotics are usually given although the results are poor. When definite softening and fluctuation occur there is no doubt that incision should be made, but in other cases it is hard to say what should be done. In the literature there is a variety of recommendations, including large incisions, small incisions, early incision and a restrictive attitude towards incision. Personally I have tried all these alternatives as well as such radical measures as acute parotidectomy an operation which is surprisingly easy in these cases, but which does not seem to change the prognosis.

Cases of chronic recurrent parotitis are often so mild as to require no treatment; but some patients suffer severe pain. Antibiotics are commonly used during acute attacks, the duration and intensity of which are seldom, if ever affected thereby. X-ray treatment may alleviate the pain temporarily in some cases. Often, ligation of Stensen's duct results in marked improvement. Sometimes, the duct recanalizes and pain recurs, but even when the ligation is definitive, periods of aching and swelling may recur. Parotidectomy is another possibility but then the whole gland and not merely the superficial part must be removed. If parts of the gland remain, the pain often recurs just as before operation. Unfortunately the facial nerve is in most cases tightly attached to the fibrotic gland. Parotidectomy in cases of chronic parotitis, is therefore technically much more difficult than when the operation is performed on a gland with a normal parenchyma.

As regards the sialosis, our choice of therapy is very limited. Some improvement can be effected in cases of collagen sialosis, if the basic disease also improves. This is particularly true of the erythematodes, in which during remission periods a normalisation of the salivary gland changes may be observed.

Cases of sarcoidosis rarely require treatment but, if indicated, it does not differ from the treatment of sarcoidosis in other organs.

When hormonal parotid changes occur it

is, of course, the underlying hormone disturbance that must be tackled. Unfortunately this is a piece of wishful thinking that can rarely be realised. Asymptomatic enlargement is perhaps also hormonal. In practice, it can be reduced to a disfigurement.

Here I should like to comment on the symptom of dryness in the mouth as well as the opposite condition, drooling—that is, xerostomia and pytalism. When it is mainly the large salivary glands that show diminished secretory ability dryness is most marked at mealtimes. The patient must drink much and often during the meal. If it is the small salivary glands that are involved and the large glands are intact, the patient suffers dryness between meals. He is almost free from dryness while eating. However usually both small and large salivary glands are affected. If the salivary glands have not entirely ceased functioning—a question which can be resolved by sialometry—some improvement can be achieved by stimulation of the secretion. Many patients feel better when they suck an acid caramel or any kind of pas-

sialosis is a myo-epithelial sialoadenitis and sarcoidosis of the salivary gland is an epithelial sialoadenitis. Therefore, I wonder if it is correct to designate these two groups as sialosis.

H Engström: I do not think that 500–700 Rad involves a risk of cancer of the thyroid gland. I think people with experience in this field would not look upon 500–700 Rad as a dangerous dose. However one should perhaps be careful not to give it to patients under 50 years of age.

T Falst: It was mentioned by Dr Enfors that ligation of the parotid duct does not always give good results. I wonder if this is due to the presence of mucus-producing cells of the parotid glands, which do not always atrophy and may later cause even large mucus-containing cysts, which spread to the neck. Has Professor Diamant seen cases like this after duct ligation, or have all cases in his experience shown more or less permanent improvement of pre-operative symptoms?

The question of ptyalism, or sialorrhoea, was taken up by Enfors. This is, of course, a rare condition, but it can be very distressing to the patient. If we exclude all cases due to toxic cancer and concentrate on the patients in whom nothing abnormal is found, is there any known reason for this condition? Could it be due to hormonal imbalance, particularly in the cortico-adrenal system, the pituitary or perhaps, in the hypothalamus? A psychic factor might possibly also account for the symptoms. I should like to know if Dr Enfors has had any wider experience with these cases. Should, for example, hypnotic treatment always be attempted before resort is taken to more radical measures, such as auriculo-temporal nerve section or extirpation of the submandibular ganglion?

Sandberg to Enfors: Impaired removal of saliva was mentioned as an apparent cause of hypersalivation. I would like to report some cases that illustrate this type of hypersalivation, in which saliva is produced in normal amounts,

but its elimination is disturbed. Two patients, both women, 43 and 63 years old, were referred to our clinic because of suspected hyposalivation. Both had been subjected to total gastrectomy with vagotomy for gastric cancer 2 and 16 months before admission, respectively. The patients complained of abundant saliva and of difficulties in swallowing both saliva and food, because swallowing took longer time than before. Physical examination revealed a moderate stagnation of saliva in the pyriform sinus, but no parotitis. Radiography of the hypopharynx, oesophagus and stomach showed normal conditions and oesophagoscopy revealed no tumour growth in the anastomoses. Intraluminal pressure recordings and recording of the deglutition pressures revealed pathological conditions with hypomotility and loss of peristalsis in the body of the oesophagus and increased tones of the pharyngo-oesophageal sphincter. The disturbed function of the oesophagus was interpreted as a reflex inhibition of oesophageal motility after vagotomy. The production of saliva was not increased, but its elimination was impaired by disturbed oesophageal function. This produced symptoms of hypersalivation.

H Diamant (Reply to Eneroth): It is true that symptomatic enlargement of the parotid glands is fairly common in some tropic diseases, and also in pronounced starvation. Cases of this sort are not found in our series. Our patients with symptomatic enlargements have always been totally healthy people. We did, in fact, take biopsies from two of those cases and sent the specimens to Professor Seifert in Hamburg. The slides showed absolute normal pictures. None of the patients were alcoholics or had other similar vices.

(Reply to Engström): I agree that there are cases of the type you described with typical benign strictures of the Stensen duct. I am also sure that in these cases a dilatation of the stricture would give a good result. In my

Fig. 10. Front page of Stenon's work on salivary glands.

title. If however secretion is greatly diminished and the mucous membranes in the oral cavity are atrophied, throat tablets may cause discomfort. Another way to stimulate secretion is to put the patient on a small dose of pilocarpine—for example 1 mg morning and evening. In certain cases the dose may without ill effects, be increased to 2 mg three times daily, but as with this dosage many patients develop tachycardia some restraint is advisable.

Drooling is another problem that is due partly to excessive secretion of saliva, but it is also necessary that the patient has difficulty in transferring saliva from the front of the mouth to the pharynx. Drooling may occur in patients with injuries in the mouth, but it also

occurs with cerebral injuries. About 10% of children with cerebral paresis have troublesome drooling.

Extirpation of the submandibular gland on one side and division of the chorda tympani on the other may be carried out with favourable results. The pool of saliva which these patients have inside the lower lip diminishes and drooling decreases. Retroposition of the orifices of the submandibular ducts back towards the pharynx facilitates movement of saliva to the pharynx, which also has a beneficial effect in many cases. The excretory ducts of the parotid gland may likewise be moved backwards, if necessary.

It is clear that we have merely touched on the more controversial forms of therapy.

Diamant: In conclusion, I cannot neglect this opportunity—especially since we are in Denmark—to pay tribute to Niels Stensen, later known as Nicolaus Stenonius, who, more than three centuries ago, gave a description of the salivary glands so meticulous that very little remained to be said on this subject (Figs. 9 and 10).

DISCUSSION

C. M. Eneroth, H. Diamant, S. Rauch and G. Selfert are the three names which are especially associated with the classification of non-neoplastic enlargements of salivary glands. I have some questions to Diamant concerning his classification of the salivary gland enlargements. Sialosis or sialoadenosis (according to Rauch painless non-neoplastic, non-inflammatory salivary-gland enlargement) have been divided by Diamant into four subgroups. The groups 1, 2 and 3 have been classified according to aetiology, whereas the fourth is the so-called asymptomatic group. Do you have another name to suggest for this group? Idiopathic enlargement is also unsuitable, because neurogenic, metabolic and deficiency diseases (protein and vitamin deficiency) are included in this group. Morphologically the rheumatic

SALIVARY-GLAND TUMOURS

CLINICAL PICTURE AND TREATMENT

T. Leegaard and H. Lundeman

From the University Clinic / Otolaryngology Ullevål Hospital Oslo Norway

A brief account is given of the incidence and localisation of the various types of salivary-gland tumours. The pathology of these tumours is in many ways interesting and partially characteristic. The clinical picture of tumours (its different localisations, the different diagnostic methods as well as prognosis and treatment of these tumours) are considered. Finally the various forms of surgical and non-surgical treatment which are available are discussed.

Diseases of the salivary glands, and salivary gland tumours in particular constitute a well-defined chapter of pathology. These tumours have many interesting characteristics, and have been increasingly studied and treated by otolaryngologists.

In the last decade, an increasing number of investigations in this field have been performed by Scandinavian otolaryngologists—investigations concerning diagnosis (sialography, aspiration biopsy), histology and pathology. Salivary-gland tumours are comparatively rare, 0.2-0.6 % of all tumours, and approximately 2 % of all tumours of the head and neck.

In Norway all malignant tumours are reported in the Norwegian Radium Hospital. For the three years 1964-1965 and 1966 the following statistics have kindly been reported to us:

Table 1. *Malignant salivary-gland tumours*

	Men	Women	Total
1964	11	16	27
1965	17	19	36
1966	9	11	20

The incidence of all salivary-gland tumours in Norway is not known, but if the malignant ones are estimated to be 15 % then we should find about 180 salivary-gland tumours annually in the whole of Norway. An important fact, shown by Eneroth (1965) should be mentioned. In the parotid, about 15 % of the tumours are malignant. In the submandibular gland, 50 % are malignant. Classification of the tumours according to pathology has for many years been very divergent, and consequently the evaluation of earlier literature is difficult. The classification used in our Department is very much like the one from the Radium-pathological Institute in Stockholm—published by Eneroth in 1964 (Table 2).

The whole of the tumour pathology cannot be considered and demonstrated in this short summary but we should like to stress our opinion concerning one particular tumour—the most common of them, the pleomorphic adenoma.

Recently as in the past, the pleomorphic adenoma has been put down as semi-malignant.

Table 2. *Classification of tumours*

experience these cases are fairly unusual. I have seen very few of them.

The ligation can always be done before a major operation like parotidectomy.

(Reply to Palva) Of course, there is a risk that a ligation in a case with too much secretion will

lead to a collection of mucus or saliva in the duct behind the ligature. I have seen this happen two or three times. It is not a great problem. In cases with normal secretion I think that a dose of 500–700 Rad can solve the problem and stop the secretion for some time and thus make the ligation more likely to succeed.

SALIVARY-GLAND TUMOURS

CLINICAL PICTURE AND TREATMENT

T. Leegaard and H. Lindeman

From the University Clinic of Otolaryngology Ullevål Hospital, Oslo, Norway

A brief account is given of the incidence and localisation of the various types of salivary-gland tumours. The pathology of these tumours is in many ways interesting and partially characteristic. The clinical picture of tumours with different localisations, the different diagnostic methods as well as prognosis and treatment of these tumours are considered. Finally the various forms of surgical and non-surgical treatment which are available are discussed.

Diseases of the salivary glands, and salivary-gland tumours in particular constitute a well-defined chapter of pathology. These tumours have many interesting characteristics, and have been increasingly studied and treated by otolaryngologists.

In the last decade, an increasing number of investigations in this field have been performed by Scandinavian otolaryngologists—investigations concerning diagnosis (sialometry, aspiration biopsy), histology and pathology. Salivary-gland tumours are comparatively rare, 0.1–0.3 % of all tumours, and approximately 2 % of all tumours of the head and neck.

In Norway all malignant tumours are reported in the Norwegian Radium Hospital. For the three years 1964, 1965 and 1966 the following statistics have kindly been reported to us:

Table 1 Malignant salivary-gland tumours

	Men	Women	Total
1964	11	16	27
1965	17	19	36
1966	9	11	20

The incidence of all salivary-gland tumours in Norway is not known, but if the malignant ones are estimated to be 15 % then we should find about 180 salivary-gland tumours annually in the whole of Norway. An important fact, shown by Eneroth (1965) should be mentioned. In the parotid, about 15 % of the tumours are malignant. In the submandibular gland, 50 % are malignant. Classification of the tumours according to pathology has for many years been very divergent, and consequently the evaluation of earlier literature is difficult. The classification used in our Department is very much like the one from the Radium-pathological Institute in Stockholm—published by Eneroth in 1964 (Table 2).

The whole of the tumour pathology cannot be considered and demonstrated in this short summary, but we should like to stress our opinion concerning one particular tumour—the most common of them, the pleomorphic adenoma.

Recently as in the past, the pleomorphic adenoma has been put down as semi-malignant.

Table 2 Classification of tumours

Mixed tumour
Papillary cystadenolymphoma
Oncocytoma
Misc. benign tumours
Muco-epidermoid carcinoma
Adenoid cystic carcinoma
Acute-cell carcinoma
Mucin-producing adenocarcinoma
Trabecular adenocarcinoma
Solid anaplastic adenocarcinoma
Misc. malignant tumours

This is probably due to its tendency to recurrence formerly often seen with these tumours. Another reason may be the postulation that the tumour becomes more malignant with each recurrence. A number of recent investigations have shown, definitely we think, that the word *semi malignant* in this connection at least, should be abolished.

The recurrences are due to incomplete removal of the tumour which has no real capsule but is not infiltrating or they may be due to the removal itself by dispersal of tumour cells in the field of operation. Furthermore several investigations have shown that the recurrences are not more malignant than the original tumour. If there is malignancy in the recurrence a reappraisal of the primary tumour will nearly always reveal the same picture there.

The distribution of pleomorphic adenomata in the various salivary glands is, according to Rauch (1959) 84 % in the parotid 8 % in the submandibular gland and 8 % in the remaining salivary glands, the lacrimal glands and the skin. If we include all tumours, 75-80 % are found in the parotid 10-15 % in the submandibular gland, 2 % in the sublingual gland and 4 % in the oral cavity and elsewhere in the body.

As far as the oncogenesis is concerned we should only like to mention the conclusion drawn by Mylius in his article of 1960. The salivary-gland tumours are all developed from mature salivary-gland tissue. Tumours consisting more or less completely of myo-epithelium including the pleomorphic adenoma originate from the interlobular ducts in the large salivary glands, or from "the neck zone" in the smaller ones. The resemblance observed between some salivary-gland tumours and tumours of the lacrimal glands, the sebaceous glands and the mammary glands is due to one common factor the myo-epithelial cell.

SYMPTOMATOLOGY

We have already mentioned that by far the greatest number of tumours are found in the

parotid and we think it proper in a brief review to speak mainly of the symptoms of the parotid tumour. The greater part of these tumours originate in the superficial and caudal part of the gland and most frequently the presenting symptom is a lump in the region of the ear. We think it is a good practical rule to consider every "lump" every tumour thus localised as a probable tumour of the parotid. Only by thinking in this way can an adequate treatment be assured. Too often these tumours are still mistreated "I thought it was only a simple superficial tumour"—and consequently the removal will not take place in a manner necessary to prevent recurrence. The symptomatology is, on the whole, not very impressing. Slow or rapid growth is by no means diagnostic. Rapid growth need not necessarily be caused by a malignant tumour. Infection of the glandular tissues and ducts can very easily confuse the picture.

On the other hand, slow growth does not of necessity imply only a benign tumour. Inspection and palpation are important. A pharyngeal extension of the gland could be inspected in the tonsillar region. Colour changes are seen in haemangiomas. Note if the surface is smooth, tuberosus, fluctuating, hard etc. Pain need not point towards malignancy. A benign tumour located in the deep part can sometimes give a painful mastoid process.

In our experience facial paralysis is seen only on very rare occasions, except in far advanced cases. It should be remembered that a malignant growth can circumvent a nerve branch without causing nerve symptoms.

Sometimes a tumour in the deep portion of the gland can increase to such an extent that the superficial part is greatly compressed and the tumour is falsely considered to be superficial. Such a tumour will displace the facial nerve laterally, stretch it and produce an abnormally ascending trunk which can easily become injured if the true situation is not realised. On the whole, we should like to stress as most important the clinical investigation. In our clinic we are of the opinion that a suspicious

hump or a probable tumour in this region should always have the surgical treatment necessary for a tumour.

However other methods should sometimes be considered to confirm the diagnosis, if possible, and to clarify the situation. So, which are these methods? Radiography and sialography have, to us, given little help. We do not think that these methods give much information in addition to the clinical findings. Sometimes, a chronic infection can give a picture very similar to that of a tumour.

We have not used *sclutigraphy* for tumour diagnosis, but this method obviously provides a possibility of disclosing the function of the gland.

Aspiration biopsy is much favoured in some places, especially in Sweden. In Norway the pathologists have been more reluctant, partly because they feel that the cytological diagnosis is far less decisive than with the whole specimen, and partly because they fear possible growth from tumour cells lost during aspiration. This last objection does not seem to be valid, and further information of aspiration biopsy will no doubt come forth later in the discussion.

We do not do a regular biopsy pre-operatively. Obviously there are too many risks associated with the opening of such a tumour. We sometimes use a freeze biopsy but, on the whole, we prefer ordinary pathological examination of the specimen, followed a few days later by radical surgery if the postoperative pathology demands it. The opportunity then exists also to inform the patient of possible disfiguring results. We do not think it justified to damage the facial nerve without the patient's knowledge of this necessity. An anastomosis, or transplantation, can be done to minimize the defect, but we at least, cannot guarantee the result, particularly if we think that postoperative roentgen treatment is necessary.

However careful the clinical evaluation and the additional investigations are, difficulties may arise, as the following case history shows.

A woman, 60 years old, had for many years had a chronic parotitis with numerous exacerbations. She was admitted to our department because she had, for a few weeks, had a new painful swelling of her parotids. The skin over the sore swelling was inflamed, and purulent secretion was seen from the orifice of the duct of Steno.

Sialography demonstrated destruction of the glandular canal system. Total parotidectomy was thought necessary and in the centre of the fibrotic, chronic affected area, we found a tumour an adenocarcinoma. Histology demonstrated typical tumour cells in the ducts.

The *treatment of choice* of a salivary gland tumour is surgery. This must be radical, i.e. the tumour must be removed together with all the glandular tissue covering it. Special attention must be paid to this rule in the most common of all the salivary-gland tumours, the pleomorphic tumour of the parotid, which, although being benign, has no real capsule of connective tissue. Mere enucleation should be considered a serious mistake.

During the operation it is very important to avoid injury to the tumour. Rupture and dissemination of tumour particles will give rise to multiple recurrences, and they are very difficult to deal with. How radical ought the operation to be? Should total parotidectomy always be done, or is it sufficient to remove the superficial portion if the tumour is located therein? Redon advocated total parotidectomy based on the assumption that multiple origins are always present in pleomorphic adenomas. Very few seem to adhere to this assumption any longer.

Is neck dissection a must in malignant salivary-gland tumours? We do not do it routinely only when suspicious lymph nodes can be felt. Roentgentherapy may be useful, perhaps chemotherapy as well. In some cases of cylindroma with recurrence we have observed more effect than we hoped for but, on the whole, salivary-gland tumours do not seem to react favourably to roentgentherapy.

Within a limited time it has only been possible to review some points about the salivary gland tumours—points which we find are of importance. We hope the following discussion will amplify and enlarge our contribution.

This is probably due to its tendency to recurrence formerly often seen with these tumours. Another reason may be the postulation that the tumour becomes more malignant with each recurrence. A number of recent investigations have shown, definitely we think, that the word semi-malignant, in this connection at least, should be abolished.

The recurrences are due to incomplete removal of the tumour which has no real capsule but is not infiltrating, or they may be due to the removal itself by dispersal of tumour cells in the field of operation. Furthermore, several investigations have shown that the recurrences are not more malignant than the original tumour. If there is malignancy in the recurrence a reappraisal of the primary tumour will nearly always reveal the same picture there.

The distribution of pleomorphic adenomata in the various salivary glands is, according to Rauch (1959) 84 % in the parotid, 8 % in the submandibular gland and 8 % in the remaining salivary glands, the lacrimal glands and the skin. If we include all tumours, 75–80 % are found in the parotid, 10–15 % in the submandibular gland, 2 % in the sublingual gland and 4 % in the oral cavity and elsewhere in the body.

As far as the oncogenesis is concerned, we should only like to mention the conclusion drawn by Mylius in his article of 1960. The salivary gland tumours are all developed from mature salivary gland tissue. Tumours consisting more or less completely of myo-epithelium including the pleomorphic adenoma, originate from the interlobular ducts in the large salivary glands, or from "the neck zone" in the smaller ones. The resemblance observed between some salivary gland tumours and tumours of the lacrimal glands, the sebaceous glands and the mammary glands is due to one common factor: the myo-epithelial cell.

SYMPTOMATOLOGY

We have already mentioned that by far the greatest number of tumours are found in the

parotid, and we think it proper in a brief review to speak mainly of the symptoms of the parotid tumour. The greater part of these tumours originate in the superficial and caudal part of the gland and most frequently the presenting symptom is a lump in the region of the ear. We think it is a good practical rule to consider every "lump" every tumour thus localised as a probable tumour of the parotid. Only by thinking in this way can an adequate treatment be assured. Too often these tumours are still mistreated, "I thought it was only a simple superficial tumour"—and consequently the removal will not take place in a manner necessary to prevent recurrence. The symptomatology is on the whole, not very impressing. Slow or rapid growth is by no means diagnostic. Rapid growth need not necessarily be caused by a malignant tumour. Infection of the glandular tissues and ducts can very easily confuse the picture.

On the other hand, slow growth does not of necessity imply only a benign tumour. Inspection and palpation are important. A pharyngeal extension of the gland could be inspected in the tonsillar region. Colour changes are seen in haemangiomas. Note if the surface is smooth, tuberos, fluctuating, hard, etc. Pain need not point towards malignancy. A benign tumour located in the deep part can sometimes give a painful mastoid process.

In our experience, facial paralysis is seen only on very rare occasions, except in far advanced cases. It should be remembered that a malignant growth can circumvent a nerve branch without causing nerve symptoms.

Sometimes a tumour in the deep portion of the gland can increase to such an extent that the superficial part is greatly compressed, and the tumour is falsely considered to be superficial. Such a tumour will displace the facial nerve laterally stretch it and produce an abnormally ascending trunk, which can easily become injured if the true situation is not realised. On the whole, we should like to stress as most important the clinical investigation. In our clinic, we are of the opinion that a suspicious

lump or a probable tumour in this region should always have the surgical treatment necessary for a tumour.

However other methods should sometimes be considered to confirm the diagnosis, if possible, and to clarify the situation. So, which are these methods? Radiography and sialography have, to us, given little help. We do not think that these methods give much information in addition to the clinical findings. Sometimes, a chronic infection can give a picture very similar to that of a tumour.

We have not used *scintigraphy* for tumour diagnosis, but this method obviously provides a possibility of disclosing the function of the gland.

An anastomosis, or transplantation, can be done to minimize the defect, but we, at least, cannot guarantee the result, particularly if we think that postoperative roentgen treatment is necessary.

However careful the clinical evaluation and the additional investigations are, difficulties may arise as the following case history shows.

A woman, 60 years old, had for many years had chronic parotitis with numerous exacerbations. She was admitted to our department because she had, for a few weeks, had a new painful swelling of her parotids. The skin over the more swelling was inflamed, and purulent secretion was seen from the orifice of the duct of Steno.

Sialography demonstrated a destruction of the glandular canal system. Total parotidectomy was thought necessary and in the centre of the fibrotic, chronic affected area, we found tumour an adeno-carcinoma. Histology demonstrated typical tumour cells in the ducts.

The treatment of choice of a salivary-gland tumour is surgery. This must be radical. I.e. the tumour must be removed together with all the glandular tissue covering it. Special attention must be paid to this rule in the most common of all the salivary-gland tumours, the pleomorphic tumour of the parotid, which, although being benign, has no real capsule of connective tissue. More enucleation should be considered a serious mistake.

During the operation it is very important to avoid injury to the tumour. Rupture and dissemination of tumour particles will give rise to multiple recurrences, and they are very difficult to deal with. How radical ought the operation to be? Should total parotidectomy always be done, or is it sufficient to remove the superficial portion if the tumour is located therein? Redon advocated total parotidectomy based on the assumption that multiple origins are always present in pleomorphic adenoma. Very few seem to adhere to this assumption any longer.

Is neck dissection a must in malignant salivary-gland tumours? We do not do it routinely only when suspicious lymph nodes can be felt. Roentgentherapy may be useful, perhaps chemotherapy as well. In some cases of cylindroma with recurrence we have observed more effect than we hoped for but, on the whole, salivary-gland tumours do not seem to react favourably to roentgentherapy.

Within a limited time it has only been possible to review some points about the salivary gland tumours—points which we find are of importance. We hope the following discussion will amplify and enlarge our contribution.

Table 3 Diagnoses in 100 cases of parotidectomy

Pleomorphic adenoma	70	Squamous-cell carcinoma	2
Adenolymphoma		Muco-epidermoid carcinoma	2
Cystadenofibroma	1	Undifferentiated carcinoma	1
Warthin's tumour	8	Cylindroma	4
Dermoid cysts	1	Adenocarcinoma	1
Cysts	3	Leiomyosarcoma	1
Lymphogranuloma venereum	1	Reticulosarcoma	2
Chronic parotitis	8		

In the University Clinic of Otolaryngology Ullevål Hospital, we serve about half a million people and we perform parotidectomy in about 25 cases annually. In addition, a small number of other salivary-gland tumours are treated surgically.

Table 3 gives a survey of 100 cases of parotidectomy performed consecutively.

The numbers in the various categories are very much like those given by Eneroth.

We think it is of major importance that patients with salivary-gland tumours are treated in hospitals and departments that are adequately equipped for specialized investigations, have the necessary surgical experience and not least, have an excellent pathological service.

DISCUSSION

C. M. Eneroth. Concerning the classification of salivary-gland tumours Professor Leegaard referred to my work on parotid tumours of 1964. We still use this classification at Karolinska Sjukhuset but with some modifications based upon our studies of salivary-gland tumours in locations other than the parotid gland. Especially among the intra-oral salivary glands there is, however, a large group of adenomata of other types than the pleomorphic (mixed tumour), oxyphilic (oncocytoma) and papillary cyst-adenolymphoma which are not included in the original classification. Since 1966, I have worked for the WHO Cancer Unit as Head of a Collaborating Centre for Salivary-Gland Tumours. The primary task is to standardize a nomenclature and to test a proposed classification by exchanging material (paraffin blocks, histological slides and diagnosis and clinical information) with other Collaborating Centres. The large group of adenomata of types other than pleomorphic and adenolymphoma has been proposed to be classified in two main groups: one according to cellular pattern in trabecular, tubular, alveolar and cystic adenoma and the other according to cell features in oxyphilic, mucous, myo-epithelial and basal cell adenoma. Furthermore, it may be questioned whether acinic-cell adenoid cystic and papillary adenocarcinomata can be sepa-

rated as muco-epidermoid carcinoma in a low-grade and a high-grade malignant type of tumour. Perhaps it may even be possible to separate a benign type of acinic-cell and muco-epidermoid tumour. However there is still difficulties in making a uniform histological distinction between the well and poorly differentiated muco-epidermoid tumours.

If these and perhaps even other problems concerning salivary-gland tumours are solved, the present classification will have to be still more modified.

J. Zajicek. The possibility of risk of tumour dissemination by aspiration biopsy is an important issue. No matter how fine the needles used for aspiration biopsy are, the procedure will inevitably produce microtrauma in its passage through the tissue, with consequent risk of tumour spread locally through the needle track or distally through punctured blood or lymph vessels. The risk of local tumour dissemination due to aspiration biopsy was investigated in pleomorphic adenomata (mixed tumours) which, because they are encapsulated, are well suited for such a study. Follow-up of 141 patients for at least five years after aspiration biopsy has shown no local recurrence after surgical removal of benign mixed tumours (Eneroth & Zajicek, 1966).

The possibility of distal dissemination through blood or lymph vessels, with its unfavourable implications for prognosis has been carefully investigated by a research group at the Memorial Hospital for Cancer and Allied Diseases in New York (Robbins *et al.* 1954

Berg & Robbins, 1962). They registered the survival times in 1406 cases of mammary carcinoma that were subjected to radical surgery and compared the survival rates of those with and without aspiration biopsy respectively. The two groups did not differ as regards 10-year survival rates. The writers therefore concluded that aspiration biopsy is not detrimental to the patient and that "clinically no reason can be found not to use aspiration biopsy when it is indicated" (Berg & Robbins, 1962).

- E. Mylius.* It must be emphasized that recurrence of pure adenomata have never been demonstrated, while pleomorphic adenomata have a frequency of recurrence of 25%. In my opinion, there is still every reason to maintain the concept of semi-malignancy.
- T. Lööfgren (Reply to Mylius).* I would like to say that the tendency to recurrence depends on the radicality of the removal of the pleomorphic tumour. These tumours have a very poor capsule, with part of the tumour sticking out in the surrounding gland.

Table 3 *Diagnoses in 100 cases of parotidectomy*

Pleomorphic adenoma	70	Squamous-cell carcinoma	2
Adenolymphoma	2	Muco-epidermoid carcinoma	2
Cystadenofibroma	1	Undifferentiated carcinoma	1
Warthin's tumour	8	Cylindroma	4
Dermoid cysts	1	Adenocarcinoma	1
Cysts	3	Leiomyosarcoma	1
Lymphogranuloma venereum	1	Reticulosarcoma	2
Chronic parotitis	8		

In the University Clinic of Otolaryngology Ullevål Hospital we serve about half a million people and we perform parotidectomy in about 25 cases annually. In addition, a small number of other salivary gland tumours are treated surgically.

Table 3 gives a survey of 100 cases of parotidectomy performed consecutively.

The numbers in the various categories are very much like those given by Eneroth.

We think it is of major importance that patients with salivary-gland tumours are treated in hospitals and departments that are adequately equipped for specialized investigations, have the necessary surgical experience and, not least have an excellent pathological service.

various series (Rawson *et al.*, 1950 Eneroth, 1964 Eneroth *et al.* 1968 and others). While invasive destructive growth is generally accepted as a criterion of malignancy other histological features, such as high cellularity, predominance of epithelial components, capsular infiltration, cylindromatous structures, incomplete encapsulation and multiple neoplastic foci are still controversial questions. As a result of this confusion, the concept of semi-malignancy has been applied to this type of tumour (Masson, 1924 Ahlborn, 1935 Rauch, 1959). However the designation semi-malignancy has, on a histological basis, in recent years been replaced by the term "pleomorphic adenoma". From a clinical point of view the concept of semi-malignancy is still of practical value, based on the tendency to recurrent growth of these tumours (Mylius, 1960). The tendency to recurrence is particularly high as compared with the monomorphic adenoma. This discrepancy is in some cases partly ascribed to multiple foci of the mixed tumours. More often it is supposed to be caused by excrescences of the marginal aspect of the tumour being left behind in the first operation. However the high incidence of recurrence is mainly ascribed to the potency of the tumour cells to proliferate in the maternal tissue following contamination of this by rupture of the capsule. In this way tumour metastases from implantations may de-

velop and may later present themselves as small tumours scattered in the previous operation area. The tendency to implanting growth of pleomorphic adenomata appears to exceed the implanting power of definite malignant tumours, and it far exceeds the implanting ability of monomorphic adenomata.

In 25 patients *monomorphic adenoma* was found (5.2 per cent of the total series). In recent years, some authors have classified these tumours with mixed tumours under the common designation of pleomorphic adenoma (Wills, 1960). When pleomorphic structures in the stroma are missing, we prefer the conventional denotation of adenoma because it represents a clinically and histologically well-defined entity. This group comprises only primary tumours, which means that they were not operated upon previously. Metastases caused by implantation were not recorded, even in cases of unsuccessful surgery in which tumour remnants had been left behind.

One tumour was classified as *oncocytoma* and another as *acinic-cell adenoma*. Both were histologically well-defined, but the acinic-cell adenoma was difficult to differentiate from the malignant type.

Adenolymphoma or papillary cystadenolymphoma (Warthin's tumour) was revealed in 23 cases (4.8 per cent of the total series).

Table 3. *Histological classification of 77 malignant tumours of the parotid gland*

PAROTID TUMOURS

CLINICAL AND HISTOLOGICAL ASPECTS

P. Berdal, H. E. Grønås and E. A. Mylius

From the Department of Otolaryngology Rikshospitalet Oslo and the Department of Pathology Sentralkkehuset Trondheim Norway

A report is given of 479 cases of parotid tumours admitted to the Department of Otolaryngology Rikshospitalet, Oslo. Mixed salivary gland tumours were present in 54 per cent. Benign tumours of other types (e.g. adenoma, adenolymphoma, angioma, cysts) constituted 22 per cent. Malignant tumours, comprising adenocarcinoma, muco-epithelioid carcinoma, cylindroma, undifferentiated—and squamous-cell carcinoma, malignant mixed tumour acinic-cell carcinoma, malignant melanoma and non-epithelial tumours, were diagnosed in 16 per cent. In 4.5 per cent of the cases the tumour appeared to be a non-neoplastic process. In the majority of cases, surgical removal of the tumour was performed. In some malignant cases, supplementary X-ray treatment was given. The tendency of recurrence of the mixed salivary gland tumours after unsuccessful surgery is stressed.

During the period 1952 to 1968 a total of 479 patients with a clinical diagnosis of tumour of the parotid gland were admitted to the ENT department of Rikshospitalet, Oslo. Surgical removal of the tumours including resection of the parotid gland or parotidectomy was performed in 434 cases. In 28 cases, the histological diagnosis was based on minor excisions.

Table 1. Survey of 479 tumours and pseudo-tumours of the parotid gland

	No.	%
Benign and semi-malignant tumours	349	73.0
Malignant tumours	77	16.0
Benign hyperplasias	14	3.0
Chronic inflammatory disorders (specific/unspecific)	2	4.5
Not classified (no operation)	17	3.5
Total	479	100.0

A survey of the series is given in Table 1. The definite neoplastic cases are divided into two main groups. Group I: benign and semi-malignant tumours, 349 cases (73 per cent). Group II: malignant tumours, 77 cases (16 per cent). A third group denoted as benign hyperplasias consists of obscure diseases, such as adenolymphoid hyperplasias (benign lymphoepithelial lesion) and lipomatosis. Chronic inflammatory disorders were found in 22 cases (4.5 per cent) comprising tuberculomata, sarcoidosis, actinomycosis and chronic suppurative inflammations. In 17 cases, the patients were not subjected to operation.

Benign and Semi-malignant Tumours

Mixed salivary gland tumours, syn. pleomorphic adenomata, are the most frequent tumours of the parotid gland and constitutes 54 per cent of all tumours in this series (Table 2). Two thirds of the patients were women. Forty-two patients (17 per cent) out of 258 had recurrent tumours, and nine of these had been operated upon repeatedly. Information about previous operations was lacking in some cases, but the predominant surgical procedure was enucleation of the tumours, involving a risk of capsular rupture and of leaving tumour remnants behind.

Opinions concerning the malignancy of the mixed tumours still differ owing to their complex histological features and variable clinical course. Malignant mixed tumours are comparatively rare, ranging from 2 to 10 per cent in

Table 5 Occurrence of facial palsy in cases of malignant tumours of the parotid gland related to death by tumour

Diagnosis	No.	Facial palsy	Died of tumour with palsy
Undifferentiated carcinoma	12	8 (66 %)	5 (5)
Cylindroma	12	3 (25 %)	3 (6)
Muco-epidermoid carcinoma	13	2 (15 %)	1 (2)
Malignant mixed tumour	5	2 (40 %)	2 (3)
Adenocarcinoma	15	1 (7 %)	1 (6)
	57	16 (28 %)	12 (22)
Squamous-cell carcinoma	7	0	(6)
Adenic-cell carcinoma	3	0	(0)
Miscellaneous	10	0	(4)
Total	77	16	12 (32)

as squamous-cell carcinoma. The tumour was highly malignant in all cases. Five patients died of the tumour within 1-2 years. In all five the tumour infiltration was extensive. On admission to the hospital, several patients had local infiltration and metastases of such an extent that curative treatment was considered futile.

Malignant mixed tumours with invasive destructive growth into surrounding tissue were found in five cases. The infiltration was predominated by the epithelial component. It was not possible to state whether these tumours represented primary malignant mixed tumours. In view of the fact that each of the five patients had had symptoms for about 20 years, it is reasonable to assume a secondary malignancy. In two cases, the tumour recurred after previous extirpation. In another case, X ray treatment had been given, and in two patients no previous treatment had been given.

The histological characteristics of *adenic-cell* carcinoma were found in three cases. Two of them are asymptomatic after 1-2 years observation. Local recurrence was seen in one case. This patient died of intercurrent disease 16 years after surgical removal of the tumour.

The group *miscellaneous* includes one lymphoepithelioma, two malignant melanomata, three malignant lymphomata and four metastatic tumours.

Involvement of the facial nerve by malignant tumours of the parotid gland usually suggests a poor prognosis. In the present series, facial nerve palsy was found in 16 patients, (Table 5) Twelve of these died of the tumour within 5 years, a mortality of 75 per cent, in contrast to 30 per cent for a corresponding group without facial palsy. The incidence of facial-nerve involvement was most frequent in patients with undifferentiated carcinomata and malignant mixed tumours.

Bilateral localisation was found in two patients. In one case the tumour disappeared gradually after biopsy and in another the tumour recurred after extirpation preceded by X-ray treatment. In one case the operation revealed macroscopic infiltration of tumour tissue throughout the gland, and histological examination showed multiple foci of lympho-epithelial tissue which could not be distinguished from the surrounding salivary gland tissue.

Malignant Tumours

Malignant tumours were present in 77 cases (16 per cent of the total series (Table 3). Adenocarcinoma constituted the greatest group among the malignant tumours, viz. 15 cases. Three of the tumours were of the cystopapillomatous type. The clinical course was highly malignant (Table 4). Two thirds of the patients died of tumour within 1-2 years. Most of the patients were treated by surgery (parotidectomy) supplemented by pre-operative or post-operative X-ray treatment.

Muco-epidermoid carcinoma was found in

13 cases. Histologically all of these revealed malignant characteristics with epithelial infiltration into the surrounding salivary gland tissue. Clinically the malignancy was moderate. Only two patients died within 1-2 years of observation.

In 12 cases the tumour showed the histological characteristics of cylindroma or adenoid cystic carcinoma. Half of these patients died of the tumour within a five year period. Although these tumours are definitely malignant, it is often difficult to get sufficient information of their clinical course, because most of them have persisted for many years before the patients are admitted to hospital. Thus, two patients who died of cylindroma had survived for 13 and 14 years, respectively after the diagnosis was confirmed histologically.

Of the 12 patients with undifferentiated carcinoma, one third died of the tumour within 1-2 years. In spite of this gloomy outlook, five patients were free from symptoms for more than 5 years after the primary operation.

In seven cases, the tumour was classified

Table 1 *Histological classification.*

Mixed salivary gland tumour	14
Muco-epidermoid carcinoma	2
Acinic-cell carcinoma	1
Infiltrating haemangioma	1
Angiofibroma	1
Neurinoma	1
Thyroid carcinoma, metastasis	1

Histologically 14 cases showed tumours of the mixed salivary gland type two cases were muco-epidermoid, and the remaining cases were acinic-cell carcinoma, infiltrating haemangioma, angiofibroma, neurinoma, and a metastasis from a thyroid carcinoma (Table 1).

The clinical problems associated with these tumours are primarily diagnosis and treatment. The diagnosis should not be too difficult, but experience shows that they are easily mistaken for tonsillary tumours. A superficial excision for biopsy may then lead to wrong conclusions. Puncture biopsy and a cytological diagnosis should preferably be made in such cases.

The treatment is mainly surgical. Patey and Thackray recommended division of the stylo-mandibular ligament to free the parapharyngeal part of the gland. In this connection, the styloid process must also be fractured in order to complete the operation by the external route. This was also recommended by Fluor in 1964.

Our methods have been somewhat different, partly adjusted during the operation when confirming the size of the tumour and the ease or difficulty in dissecting it free. In 10 of the patients, the tumour was removed by a combined transoral and external dissection. In five cases, the tumour was removed transorally and in five cases externally. One patient was not subjected to operation because of advanced age (83 years).

To achieve sufficient space for a safe approach to the tumour we have since 1957 cut the mandible just in front of the angulus (Fig. 3). After removal of the tumour the mandible is sutured with a stainless steel wire and allowed to heal per primum. The temporary cutting of the mandible does not complicate the surgery very much, and it offers to the

Fig. 2. Parapharyngeal protrusion of a dumb-bell tumour.

surgeon possibilities of an easy dissection of the tumour from its surroundings and for ensuring the integrity of the tumour. We have applied this method in six cases (Berdal, 1965). The procedure does not involve any great inconvenience on the part of the patient. A still higher degree of safety is perhaps achieved by cutting the mandible in the midline. Both the transoral and the combined transoral/external approach involve the risk of postoperative oedema with obstruction of the airway. To secure an open airway it was necessary to perform tracheotomy in eight cases, which, in our opinion, should be done in all cases.

Rupture of the capsule of the tumour occurred in six cases of mixed salivary gland tumours. The calamity leads to contamination of the operative field, involving the risk of recurrence from implanted tumour cells. In these cases, a thorough irrigation of the area with saline was performed. This procedure may reduce the danger of implantation. Follow-up

PARAPHARYNGEAL GROWTH OF PAROTID TUMOURS

P Berdal and J G Hall

From the Department of Otorhinolaryngology Rikshospitalet Oslo Norway

A total of 479 patients with tumours of the parotid gland were admitted to the Department of Otolaryngology Rikshospitalet, Oslo. Of the tumours, 21 were of the dumb-bell type, showing parapharyngeal growth. Diagnosis and operative procedures are discussed. For surgical removal a transmandibular approach is recommended.

Most parotid tumours are found superficially to the facial nerve. Among the more profoundly situated tumours, a parapharyngeal extension and protuberance develop in some cases. The anatomical and topographical background for this development of some of the parotid tumours was shown by Patey & Thackray (1957) and by Fluor (1964) (Fig. 1). A canal called the "stylo-mandibular tunnel" is formed by the base of the skull cranially, the ramus ascendens of the lower jaw and the internal pterygoid muscle ventrally and the styloid process and the stylo-mandibular ligament dorsally. The deeper part of the parotid gland may grow inwards into this canal in a

parapharyngeal direction. This probably happens because the gland laterally is surrounded by a firm fibrous capsule, while the part extending towards the stylo-mandibular tunnel is covered by a thin fascia which allows an easier growth and extension along this route. The narrow stylo-mandibular tunnel is fixing and drawing the tumour together at this point, giving it a hour-glass appearance, which is the origin of the name "dumb-bell tumour".

The lateral part of the tumour may be seen and palpated from the outside, while the medial part is seen as a protrusion in the lateral part of the fauces, where the tonsil and the palatal arches are displaced medially.

Among a total of 481 cases of tumour of the parotid gland admitted to the ENT Department of Rikshospitalet, Oslo 21 tumours of the dumb-bell type were found. Fifteen of these could be seen both parapharyngeally and in the retromandibular fossa. In six cases, the tumour was only seen parapharyngeally (Fig. 2). Eleven of the patients had noticed a swelling of the throat or difficulty in swallowing. Another four patients had pain or an uneasy feeling in the throat, six had a feeling of stuffiness in the ears or were hard of hearing.

The duration of the disease from the onset of the first symptoms until operation was less than 12 months in 14 cases. In four it was between 4 and 5 years, in two between 8 and 10 years, and the last patient represented a recurrence after an operation performed 23

Fig. 1 Stylo-mandibular tunnel (after Fluor 1964)

DISCUSSION

C. M. Eneroth. In the reported series from Rikshospitalet, Oslo, it is a surprisingly high

frequency of parotid lesions bulging into the pharynx—21 of 481 cases. The great majority of parotid tumours (80–90 %) are localized in the superficial lobe. Of the tumours in the deep lobe, only a few attain such a size that they fill the parapharyngeal space, causing the pharyngeal wall to bulge in medially.

In a study of the incidence of parapharyngeally growing parotid tumours, 1108 cases of parotid tumours operated at Karolinska Sjukhuset, were analysed. Nine of them—thus less than 1 %—proved to be clinically parapharyngeal, i.e. a much lower frequency than in Hall's series. A remarkable fact is, however, the agreement between the two series concerning the types of parapharyngeally growing parotid tumours. In Hall's case material three types were represented: mixed tumour, acinic cell and muco-epidermoid carcinomata, and in my own from Karolinska Sjukhuset there were two types, namely mixed tumour and acinic cell carcinoma. This can be explained by the fact that the different types of tumour represented in the two series are slow-growing and usually asymptomatic on growth into the pharynx. On the other hand, the highly malignant types of tumour come under treatment before they reach such a size because of their greater variety of symptoms, in the form of, for example, nerve infiltration and metastases.

The difference in frequency of parapharyngeally growing parotid tumours in the two series can perhaps be explained by a shorter pre-operative tumour duration in the case material from Karolinska Sjukhuset, i.e. the patients have come earlier to diagnosis, before the tumours have reached such a size that they bulge into the pharynx.

J. G. Hall (Reply to Eneroth). I did not mention the duration of the symptoms in my Norwegian paper, but it will appear in the English text. As to your question, the point may be that the duration of the symptoms is sometimes longer than the patients seem to recognize.

LIPOMATOSIS OF THE PAROTID GLAND

J. Johansen and P. Berdal

*From the Department of Otolaryngology and Surgical Pathology
Rikshospitalet Oslo, Norway*

During the period 1952-1968 a total of 462 patients with tumours of the parotid gland were subjected to operation in the Department of Otolaryngology Rikshospitalet, Oslo. In three cases, histological examination revealed lipomatosis of the parotid gland associated with local subcutaneously increased fat deposits.

Case 1 A girl aged 2 $\frac{1}{2}$ years of healthy family was admitted in the department on Nov. 16, 1967 for treatment of tumour of the right parotid gland. There were no remarks on pregnancy birth or neonatal period. She had been in good health with normal growth and development. In November 1966 the parents discovered swelling in front of the right ear. An older sister suffered from epidemic parotitis at that time, and so the swelling was considered to be of infectious origin. As the swelling did not disappear but contrarily slowly increased in size, the patient was received in our department.

Physical examination showed firm, non-tender smooth tumour apparently invading the skin and the glandular tissue, extending from the right mandibular angle to the zygomatic arch. The parotid duct and the secretion seemed unaffected. No parapharyngeal involvement and no lesion of facial nerve was seen. The results of routine laboratory studies, including blood-cell counts and paper electrophoresis of serum proteins were normal. Stalographically the tumour was seen to be closely connected laterally with the parotid gland.

After observation for 3 months in our out-patient clinic, the tumour appeared to increase in size with distinct infiltration of the skin. Subtotal parotidectomy and excision of the tumour were performed. The operation revealed yellowish firm tissue forming tumour-like mass with infiltration into the parotid gland and the overlying fatty tissue.

Pathological examination showed a lobular glandular architecture with islands of acinar cells surrounded by numerous large fat cells. The ductal system seemed normal, perhaps with some proliferation of small ducts. Angiomatous proliferation was not seen (Fig. 1).

Case 2 A woman, aged 43 married, four children, several abortions, operatively sterilized, of healthy ancestry.

The patient was admitted to the department on June 14, 1968, for surgical treatment of a tumour in the right parotid gland, rapidly developed.

Clinical examination showed 5 x 4 cm, non-tender firm, movable tumour relatively well demarcated, in the right parotid area. The parotid duct and the secretion seemed normal. There was no parapharyngeal growth, no involvement of the facial nerve.

The results of routine laboratory studies were normal. Stalography confirmed the diagnosis of tumour laterally in the parotid gland.

Operation disclosed fairly well circumscribed partially encapsulated yellowish tumour of firm consistency. Histological examination revealed lipomatosis of the parotid tissue. Acinar cells formed small strands and islands between large fat cells, which appeared to have replaced most of the normal acinar cells. The ductal system seemed largely normal, perhaps with some proliferation of smaller ducts. Angiomatous proliferation was not seen (Fig. 2).

Case 3 A married woman, aged 36, one child, was admitted for operative treatment of repeated recur-

Fig. 1 Lipomatosis of the parotid gland. Numerous fat cells are seen surrounding islands and strands of acinar cells. Ducts of varying calibres (Case 1).

Fig. 3 The mandible, cut in front of the angulus.

examinations of these patients have not disclosed any new growth. They were seen after 9 6 4 4 3 and 1 year respectively. Neither in any of the other cases did the tumour recur after extirpation. The observation periods vary from 1 to 12 years.
